Thorax.—The abdominal viscera, the liver especially, pushed the diaphragm high up into the chest. The pericardium contained at least four ounces of bloody serum. The heart was enlarged, and the vessels on its surface were much congested. The walls of the ventricles and auricles were very thin and flabby; and each of the cavities of the heart was very full of dark fluid blood. In the right cavity of the thorax there were six ounces of bloody serum. The pleura was every where very red. The pleura costalis and pulmonalis, on the left side of the chest, were, for the most part, closely united together by old adhesions. The vessels of the right and left lung were very much congested; and a quantity of frothy bloody fluid escaped from them when an incision was made.

Trachea and Bronchia.—The membrane of the trachea and larger bronchia was very red, but contained little fluid. On tracing the ramifications of the bronchia into the lungs, the same redness of the mucous membrane was observed; and the air cells were choked up, being quite filled with a frothy bloody fluid.

Abdomen.—The liver was rather large and soft, but otherwise healthy. The peritoneum was generally healthy. The spleen and pancreas were healthy, but their peritoneal investment was very much congested with blood; so much so, as to resemble the pia mater. The peritoneal covering of the small intestines was congested. A portion of the jejunum, and a portion of the ileum, were examined, and contained a pinkish-coloured chyme; but the mucous membrane of the bowels was not diseased.

Kidneys and Organs of Generation.—In the capsule surrounding the kidneys, particularly on its anterior part, there was a considerable extravasation of blood. The left kidney was large; its vessels were very much congested; and the membrane lining the pelvis was very red, and bloody fluid was contained in it. The right kidney was still more inflamed, and the pelvis containing at least two drachms of blood. The bladder contained two ounces of blood; its lining membrane was very red. The lining membrane of the uterus was also red. The ovaries were much inflamed, and in the right ovary there was a considerable extravasation of blood. The fallopian tubes were inflamed. The hymen was entire. The stomach contained about a pint of fluid, about as thin as gruel, but of a brown colour; there were also mixed with it several dark-coloured spots, which fell to the bottom of the fluid. Several of these dark-coloured pieces of matter were also found in the track of the intestines*.

The whole of the membrane of the stomach was very red; and there were numerous dark chocolate-coloured spots, arising from extravasation of blood into the sub-mucous membrane, throughout every part. These spots varied in size, from a small speck to that of the circumference of a horse-bean.

Brain.—The brain itself was healthy, but the blood-vessels were every where much loaded with blood. The plexus chorioideus was of a very deep colour; and the veins ramifying on the pia mater were dilated to a very large size, and were full of dark blood.

The verdict of the Coroner's jury was, "died by the visitation of God;" and Dr. H. concludes the case with some observations, in which he lays principal stress on the inflamed state of the stomach, kidneys, and bladder, as giving rise to the vomiting, pain in the back, and straining; and on the congested state of the brain and lungs as the cause of the fatal convulsion. There was besides, as was properly remarked, no circumstantial evidence whatever of poison having been administered; and in the absence of such proof, notwithstanding the strong resemblance of the symp-

* Some of these particles of dark matter were minutely examined; but neither by the naked eye, nor by the microscope, could that resplendent appearance which characterises cantharides be detected. The matter seemed, indeed, readily to rub into a black powder, and was doubtless the dark gritty matter which is so frequently mixed with coarse oatmeal, as the patient had, during her illness, taken freely of gruel made of coarse oatmeal.

toms to those produced by cantharides, it was only fair to conclude that death had resulted from natural disease.

Case of Osteo-Sarcoma of both Jaws.

By MR. HETLING, of Bristol.

This is a very elaborate paper, which may be consulted with advantage for its bibliography, and the quantity of information which it contains relative to operations for osteo-sarcoma. Mr. Hetling proves that tying the primary carotid, previously to the removal of the tumor, ought to be discountenanced as a proceeding of great danger; and he shews that not only both jaws, but "almost the entire of one side of the bones of the face, may be safely amputated, and the patient still be able to perform the functions of mastication and articulation, accompanied with but slight deformity."

Case of Melanosis. By DR. D. WILLIAMS, of Liverpool.

The history of this case is well related, and illustrated by a coloured portrait. The subject was a coal-miner, about 30 years of age. The external development of the disorder continued for about two years: what changes took place internally it is greatly to be regretted that we cannot know, as the friends of the deceased refused to allow an examination after death.

Case of Hydrocephalus. By DR.

TRAILL, late of Liverpool.

The treatment adopted in this case appears to have been so judicious, and the event so encouraging, that we give it at length.

William Da C. æt. 20 months, previously a fine healthy boy, became the patient of my friend, the late Mr. Reay, on the 24th of April, 1830. He then laboured under a slight remitting febrile attack, seemingly arising from the state of his digestive organs, attended with some cough, and occasional fits of screaming. Calomel with jalap, scammony, and antimonial powder, were successively administered, with relief to the symptoms, but still the remittent fever continued; and Mr. Reay perceiving some tendency to squinting, began to dread that it would terminate in hydrocephalus, and I was called in on May 14th, when I found the child very hot, with a rapid pulse; the alvine discharges ill digested and extremely offensive; the abdomen, though not tumid, felt doughy or inelastic; the tongue was furred; there

was no marked impatience of light; the pupils regularly contracted, but the child occasionally screamed without apparent cause, and the urine was scanty. He had cut all the incisors, the canine teeth, and four of the first molares; smart doses of calomel and jalap, with a mixture containing squill, were prescribed, while the head was ordered to be kept cool by an evaporating lotion. 15th. Bowels freely moved, fever diminished, stools improved. 16th. At one this morning I was summoned, and found the child in a severe convulsive fit. Gums immediately freely divided, over the concealed molares. Leeches to the temples. Enemata. The warm bath. Dose of castor oil.

17th. To-day decided symptoms of cerebral affection were present; impatience of light; frequent screaming; convulsive twitches of the limbs. Leeches again applied, and a large blister between the shoulders, reaching to the nape. Cold evaporating lotion to be kept constantly applied to the head. Calomel and jalap in repeated doses. 18th. Blister rose well, the cuticle was removed, and the raw surface dressed with unguentum hydrargyri. 19th. Symptoms unchanged. The action of the bowels kept up by small doses of hydr. c. creta three times a day. To-day there is strong strabismus; pupils much dilated, and nearly insensible to light. Yesterday and to-day all the other bad symptoms were increased; screaming more frequent; left side seemed paralytic, while the limbs on the right side were frequently and convulsively agitated. 20th. No improvement; cont. medicamenta. 21st. Repeat the blister as before, and again dress it with the mercurial ointment. Give a dose of castor-oil, to purge the bowels. 22d. Bowels active; omit the hydrarg. c. creta; if necessary, give an enema. In the evening castor-oil. Pulse, which had been rapid generally, now between 70 and 80. Omit the cold applications to the head. 23d. No improvement; urine nearly suppressed; eyes quite insensible to external objects, but he can swallow easily; calomel and jalap purge; enemata; nitre whey. 24th. Moaning and screaming very distressing; urine very scanty; one side quite paralytic, the other constantly agitated by convulsive twitches. Repeat the blister, and dress it as before. Bowels rather costive. Castor oil and enemata. Omit the purgative powders. 25th. The child begins to be under the mercurial influence; blistered surface highly inflamed; simple cerate substituted for the mercurial ointment; enemata as before; convulsive motions less violent. 26th. Less convulsion. Cont. omnia ut heri. 27th. Urine considerably increased. Cont. 28th. Some undoubted signs of improvement; urine pass-

ed freely; twitching of limbs and screaming less violent; one of his front teeth loose; gums swelled; bowels freely open; some griping. Omit the castor oil. A few drops of tinct. camph. comp. to be occasionally given. 29th, 30th, 31st. Improvement progressive, but slow; twitching and screaming much less frequent; nape of neck much inflamed, and discharging freely; bowels open; some griping; urine copious; the paregoric appears to soothe him; anodyne at bed-time. June 1st. Favourable symptoms continue, but the eyes appear insensible to light, and the strabismus continues; pulse below 70, rather irregular. Conceiving that the inflammatory stage had subsided, but that the ventricles were still loaded, diuretics were continued, and a small blister was applied to the vertex, over the fontanelle, in the hope of promoting absorption. The bowels open, but much distended with flatus, for which a foetid enema was given with relief. 2d. Seems relieved; an opiate was given to-day, which allayed the convulsive motions of the limbs. 3d. Repe- tantur enema foetidum, et haustus anody- nus. h. s. 4th. Strabismus much diminished; urine in large quantity. Cont. omnia. 5th. Blister on vertex repeated. Bowels bound. Castor oil. 6th. Evident improvement in every respect. He now can distinguish external objects. The loose front tooth was removed by the fingers from the lower jaw, without pain to the child; its root was long, white, and hollow. 8th. Eyes and limbs gradually recovering; urine very copious. 11th. Child so far recovered that I discontinued my evening visits. An astringent lotion was prescribed for the mouth; the bowels being sluggish, a dose of castor oil was recommended every second day. After the 18th I only saw him twice professionally; Mr. Reay ceased to attend him on the 11th July, and he was soon in vigorous health. The boy remains quite well, and has no mark of having suffered from disease, except the loss of the two front teeth of the lower jaw; the second having been shed in the end of 1830. His countenance is naturally pale, but he has a healthy look; his limbs are strong and muscular; his habits active and lively; his intellect very acute.

There are a number of other valuable papers in the volume, which we shall probably take a future opportunity of noticing. We will now only stay to add, that there are here also some medico-statistical reports, contributed by Mr. Middlemore, Mr. Parsons, and Dr. Streeten, which in our eyes greatly enhance the merit of the publication.

Johannis Caii Britannii de Ephemera Britannica Liber. Recudi curavit J. F. C. HECKER, Med. Prof. in Univ. Berolinensi.

This is a very neat little reprint of the *Ephemera*, and does great credit to the editorial zeal and ability of Dr. Hecker. It is taken from the edition of 1721, the latest published in this country, and which has become extremely scarce. In his researches on the pestilences of Europe, the author of the Black Death became acquainted with the account of the Sweating-sickness (*Ephemera*) given by our countryman, and finding it not voluminous, and at the same time worthy of being better known, brought it out in its present convenient form. He has been engaged, it appears, for some time, in writing a history of the Sweating-sickness, and he intimates that he has procured, in the course of his inquiries, materials far more valuable than those of Caius. The latter describes the pestilence of 1551; but Dr. Hecker informs us that he has lighted on a German writer, Schiller, who gives a full account of the visitation which afflicted this country in 1529. Meantime, till the promised history is published, Dr. H. requests the reader to suspend his judgment respecting the English Sweat.

Dr. Babington, in the appendix to his translation of the Black Death, gives a specimen of Caius's *Boke or Conseill against the Disease commonly called the Sweat or Sweating-sickness*, 12mo. Lond. 1552. The work before us is the Latin version of the said *Boke*, published by the author himself a few years later. We need not go into an analysis of its contents, partly not to anticipate the promised details of Dr. Hecker, but more particularly as the curious reader will find it already amply done by Dr. Aikin, in his Biographical Memoirs of Medicine.

M. VELPEAU'S NEW WORK.

Embryologie, ou Ovologie humaine, contenant l'Histoire descriptive et iconographique de l'Œuf humain. Par A. L. M. VELPEAU, Chirurgien de l'Hôpital de la Pitié, &c. &c. Fol. accompagnée de quinze planches. Paris, 1833.

In this splendid work, which is just published, we find a full historical account

of the various opinions which have been maintained at different times by anatomists respecting the structure, development, and connexions of the human placenta. Arantius, Hoboken, Warthon, Ruysch, Malpighi, the Hunters, Wrisberg, Reuss, Lobstein, Meckel, and many others, have made numerous efforts to discover the nature and structure of this organ. In this respect, observes M. Velpeau, we might have hoped that science had nothing further to desire; but in perusing the most esteemed writers on the subject, we are soon undeceived by discovering that at least twenty different opinions still have their antagonists and their defenders.

M. Velpeau, who has devoted for many years much attention to this and all other subjects connected with embryology, strongly supports the opinion that there is no connexion by great blood-vessels between the uterus and placenta, and that there are no cells in its structure. He is also of opinion that lymphatics do not exist in the placenta, as Professor Lauth has described.

After alluding to the experiments of the Hunters, Dubois, Chaussier, Denéau, Williams, &c. in which the injections sometimes passed, not only into the substance of the placenta, but into the blood-vessels of the fœtus, M. Velpeau observes, "But it appears to me that a false estimate has been formed of the importance of such experiments, for they are not applicable to the living subject. The passage of an extraneous fluid, when forcibly pushed forward into vessels, does not unquestionably prove that during life the course of the blood is the same. When we throw a fine injection into the arteries of the abdomen, the matter is quickly extravasated on the internal surface of the intestines. Introduced by the vena portæ, it returns, not only by the veins and hepatic artery, but further, by the excretory canals of the bile. Thrown into the renal artery, it passes quickly into the emulgent vein, and also into the pelvis of the kidney and ureter. Nevertheless, we do not conclude that during life the blood continually transudes into the alimentary canal, that it passes from the vessels of the liver into the hepatic ducts, or from the kidney into its excretory passage. Oil, glue, mercury, employed by Chaussier, Williams, &c. are substances of too subtle and penetrating a nature not to

go wherever we desire them, but their passage will never suffice to resolve the difficult problem of the connexion between the mother and child."

Besides, says M. Velpeau, what necessity is there for injections in such an inquiry, where the naked eye can see all the objects, where the senses are sufficient to prove at the first inspection, not only that there is not, but that there cannot exist a vascular continuity between the uterus and placenta? M. Velpeau declares that injections are only calculated to lead to confusion and error.

It is obvious, we think, from this short account of the opinions of this distinguished author, that the question of the nature of the connexion between the mother and child is not likely soon to be set at rest either in this country or on the continent. About a month ago, before the preparation at the College of Surgeons was examined by Messrs. Stanley and Mayo, we understand that Dr. Robert Lee, in order as far as possible to obviate every fallacy, examined a gravid uterus in the eighth month, in which he had previously coagulated the maternal blood. He was able to satisfy himself and Mr. Lawrence, who was present at the examination, that coagula of the maternal blood extended from some of the openings in the lining membrane of the uterus into canals formed by the deciduous membrane on the margin of the placenta. These vessels or channels in the decidua could be traced only a short distance along the margin of the placenta, and between the lobes.

As Dr. Lee, we believe, is still engaged in investigating the subject, we feel convinced, from his known love of science, and from the candour of his disposition, that as soon as he has arrived at any satisfactory results, he will give them to the public, whether they should be consonant or not with the opinions he has promulgated in his paper in the *Philosophical Transactions*.

The work of M. Velpeau displays great learning and research, and deserves an attentive examination: we shall take another opportunity of giving it a more extended notice.

MEDICAL GAZETTE.

Saturday, June 29, 1833.

“Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso.”

CICERO.

THE MEDICAL CORPORATIONS
AND THE APOTHECARIES' BILL.

THAT is done at last which ought to have been done at first—the Bill is referred to a select committee. The proposed Act, with the several amendments to which we adverted last week, has been printed, and now lies before us; but, as we then predicted, the Scotch are dissatisfied with it; and we believe that, partly owing to this circumstance and partly in consequence of a remonstrance from Dublin, the right honourable Under-Secretary for the Home Department became completely *bothered*, and resolved to get rid of the matter in the way above-mentioned. When the report is presented, we shall know more about it; but to us it is very doubtful whether any thing will now be done this session: meantime, we have a remark or two to make with regard to the part taken by the two other corporate bodies on this occasion—namely, the College of Physicians and the College of Surgeons; towards both of whom, by the way, language far from laudatory was made use of in the House, and marvelously well received by the honourable members present. Pretty strong proofs these of the temper of the times*!

The former learned body, with that dignified indifference and aristocratic apathy which originally led them to suffer the licensing of practitioners in physic to pass into other hands, thought it most expedient on this occasion to do nothing;—the fittest course, perhaps, for a corporation which, from the highest place in influence and utility, has, by its own supineness and narrow policy,

sunk so low, that while it retains the empty honour of its rank, it has virtually become a mere cypher in the medical republic. But we forget; their interests were not compromised by this bill: one honourable member, more friendly and considerate than the rest, insisted upon it that a clause should be introduced, entitling the Fellows of the College to practise as apothecaries, and even to claim an examination at Blackfriars, on the strength of their residence at Oxford or Cambridge, without having served an apprenticeship! Whether the honourable gentleman made this proposal in pure simplicity or in irony, we have been unable to ascertain, but in neither case probably will the College thank him for his exertions in their behalf.

Turn we now to the College of Surgeons. Did they, too, refuse to give any opinion, and to take any part? No,—they know better what they are about. They saw that something was to be gained; they exerted themselves, they conferred—with each other—with the apothecaries—with active members of parliament—they had a deputy in the House during the discussion, and so far as the arrangements had gone, they had gained their object. Their diploma, as the Bill is now framed, stands in place of an apprenticeship, which it ought to do; and in place of attendance on the practice of physic—which it ought not to do. The words are:—

“And be it further enacted, that every person who has obtained or who shall hereafter obtain the diploma of either of the Royal Colleges of London, Dublin, and Edinburgh, or of the Faculty of Physicians and Surgeons of Glasgow, shall, upon the production of such diploma, and a certificate of having attended for at least twelve months at the laboratory of a surgeon or apothecary, or of a public hospital or dispensary, be admitted to examination by the Examiners appointed by the Master, Wardens, and Society of Apothecaries of London, for the certificate of his qualification to practise as an apothecary.”

* See the Parliamentary Orders at page 447.

Now this distinctly places the regulation of the education of the general practitioner in the hands of the College of Surgeons, with the single condition that their diplomatist shall also have attended in a laboratory for twelve months. It is understood, indeed, that the College of Surgeons have agreed to require attendance during a certain period on the practice of medicine, as well as surgery; *but it is not in the bond*; and there can be no reason for inserting the attendance on pharmacy, and omitting the attendance on practice, except to leave it in the power of the surgeons to require as much or as little physic, or none at all, as may suit the ideas of the Council for the time being. Against this we must enter our protest. The point in question is not less important than a knowledge of pharmacy, and if this was deemed fit to be inserted in the Bill, so ought the other. Many of the Council are enlightened men, and we doubt not would, as a matter of conscience, require that of their diplomatists which they are not bound to do by the letter of the Bill; but we also know that there are others among them of a different stamp—confident, conceited gentlemen, who know not enough of physic to be aware of their own ignorance. Besides, there is withal an *esprit de corps* which naturally, we might say necessarily, biases them in favour of surgery; and the result will be, if the Bill pass without a specification as to the *medical* part of the pupil's education, that our general practitioners will be good surgeons and bad physicians. Now herein is apparent the injury to the profession generally from the supineness of the College of Physicians, which leads to others being suffered to regulate what properly belongs to them. Had they used the influence which they still possess—had they co-operated with the Apothecaries in representing in the proper quarter that general practitioners attend nineteen

medical for one surgical case, it certainly would not have been left optional with the gentlemen in Lincoln's Inn Fields to prescribe for the education of those who are to be the physicians of all but the most wealthy classes;—and as a matter of course to require of them the greatest possible proportion of surgery, and the least possible proportion of medicine. It is said, we know not how truly, that the Apothecaries have agreed that the attendance on *surgical* practice should so far stand in lieu of *medical* practice as to have this diminished to one half of what they at present require. If this be so, it is an abandonment of their duty, and a tacit acknowledgment that they have heretofore required too much.

The Apothecaries, again, we are told, assert that they do not so understand the arrangement, and assume that the College of Surgeons are to append to their "regulations," that the candidate shall have studied the practice of physic at the bedside of the patient, where alone it can be learnt, for the same period as heretofore enjoined at Blackfriars. But there ought to be no *understanding* about the matter, else assuredly shall we have *misunderstanding*. Whatever is to be, ought to be placed beyond the possibility of future cavil. The practice of pharmacy is inserted in the Bill, because it is admitted to be necessary; and the medical practice can only be left out because it is not admitted to be so. The Apothecaries ought to insist on having it in the Bill, or to throw up their charge, for without it their power over medical education is annihilated; and a general practitioner will then be = M.R.C.S. + a certificate of a year's attendance in a laboratory.

Again, the Society of Apothecaries require two courses of lectures on *materia medica*; the College of Surgeons only one. Are the former to give up

one of their courses, or the latter to add another? The power of determining the point rests exclusively with the College of Surgeons, who may strike lectures on materia medica, and the practice of physic too, out of the list altogether; and yet, possessed of their diploma, the Apothecaries dare not refuse to examine the parties. It would be a mere absurdity for the Society of Apothecaries to issue any regulations for the education of their licentiates; they must be content to follow the curriculum of the Surgeons, and to make their own subservient to it; for it is not to be supposed that any aspirants will take a circuitous route to Blackfriars, when a direct and shorter course is open to them through Lincoln's-inn Fields. Thus, therefore, it appears, either that the education which shall qualify for examination at the College of Surgeons ought to be specified, or that it ought to be left to the Society of Apothecaries to require certain branches in addition, should the diplomatist not previously have attended them; and for this, it behoves the Apothecaries to make a stand.

We do not blame the College of Surgeons farther than that they have been too grasping. What they have done is in the natural spirit which actuates all corporations—to increase their own power; and we allow, that their declining to demand what the Edinburgh College so modestly required, has probably been the means of gaining for the Apothecaries such terms as they are likely to obtain, so strong at first was both the prejudice against them, and the ignorance of the merits of the question, among the members of the government. The College of Surgeons have shewn great activity, and a quick perception of their own interests on this occasion. Indeed, had they been but half as zealous in carrying into effect their long talked of improvements, they would have had

nothing to fear from any parliamentary investigation. For the College of Physicians we cannot say so much: in fact, they have displayed just the reverse of all these qualities; and as they formerly declined to interfere with regard to the Apothecaries, it only now remains that they should pursue their negative policy a little longer, till the power of ordaining physicians be placed in other hands; and thus reap the full benefit of—non-intervention.

PIRACIES OF THE LANCET.

WE have to notice one of those instances of knavery so disgraceful to literature, by which editors, who are at once dishonest and distressed, occasionally contrive to appropriate to themselves the property of others. We allude to the *Lancet*, which, in the dearth of correspondents of its own, has of late adopted the expedient of filling its pages by copying from its neighbours. Of six borrowed papers, which the last number alone contains, the sources whence they are taken are acknowledged with respect to all, save one; namely, that of Messrs. STANLEY and MAYO, published by us; while the same journal of the week before contained Dr. H. LEY's essay on the Placenta, also copied verbatim from the MEDICAL GAZETTE, *typographical errors included*. Now when the systematic and rancorous hostility of the *Lancet* towards this journal is considered, it cannot but be regarded as an extraordinary tribute to the superiority of our materials, that it should thus have recourse to them for assistance in its own necessities. But when we add that our articles are taken without any reference to this journal, and with the deliberate falsehood appended that they have never before been published, it constitutes an example of such a total want of all honourable feeling—of so much

meanness, combined with so much dishonesty, as no other periodical professing to be devoted to science, has ever displayed. We are of course aware that the purposed defence of this piece of literary swindling is, that what appears in this journal is not *published*,—a specimen of chicanery, which, when first adopted, we disregarded, as in keeping with the known propensities of our contemporary, and by which, therefore, we could sustain no injury; but when we find the principle acted upon as a pretext for deliberate piracy, we feel called upon, in justice to ourselves, to denounce it. Having done this, we take leave of the subject for the present; meantime, it must be gratifying to the Editor of the *Lancet* to reflect, that he has thus brought upon himself an exposure of the poverty and trickery of his paper, which will be more extensively circulated among the members of the medical profession, than his edition of the pirated essays.

HARVEIAN ORATION.

THE anniversary tribute to the memory of the great Harvey, or, as it is usually so ordered, the commemoration of the founders and benefactors of the College, and yearly *elogé* on distinguished professional characters deceased, was delivered on Tuesday last by Dr. Paris. There are so many associations connected with the delivery of a Latin oration from a rostrum—the orator clothed in his doctoral scarlet robe, and listened to by a grave assembly in a splendid and spacious apartment—that to say the effect was imposing, would go but a short way in describing the feelings which, we are sure, are generally excited on such an occasion. But however brief our notice of such points may be, we must do Dr. Paris the justice to declare, that independently of all such external

attraction, his address was a very admirable one, whether we regard the well arranged and interesting matter of which it was composed, the classical correctness and elegance of the language, or the dignified and appropriate manner in which it was pronounced. The parallel between the illustrious Drs. Wollaston and Young was forcibly drawn; and the valedictory panegyric on the late lamented Dr. Babington, was as just in sentiment, and as chastely conceived, as it was feelingly expressed. An involuntary murmur of applause followed this part of the oration.

COLLEGE OF PHYSICIANS.

Monday, June 24.

THIS was the last of the evening meetings for the season. In the absence of Sir Henry Hallford—an absence, we regret to learn, occasioned by a domestic calamity—the chair was taken by Dr. Maton. The attendance of members of the profession was large, and we observed not a few distinguished visitors present. The paper read was entitled,

Observations on the present state of Toxicology, with especial reference to a New and Simple Method of Detecting Metallic Poisons. By JOHN CLENDINNING, A.M. M.D. &c. &c.

The author (who, by the way, read his own paper from the rostrum) commenced by acknowledging himself indebted to the President for his encouragement and example in taking up the subject of poisons to lay before the meeting. But his (Dr. C.'s) object specially was to recommend to the notice of his professional brethren an easy method of detecting metallic poisons through the agency of Voltaic electricity. He had been engaged for some time in the examination of this method, and had obtained results which he humbly presumed were deserving the attention of the public.

Dr. Clendinning then begged to remind his auditors of the principal modes of testing metallic poisons which were

in use at the present day, in order to contrast with them the simplicity and facility of the electro-chemical method. With regard to arsenic, the progress made of late years in improving the method of reduction has been very remarkable. In the year 1786, when Hahnemann's work, *Ueber die Arsenikvergiftung*, appeared, not less than eight or ten grains of the oxide were required for a successful experiment; but Black, Berzelius, Christison, and Orfila, have so perfected Hahnemann's, or rather Pyl's, method (that of deoxidating by heat applied to a retort), that, at the end of fifty years from its first trial, it has been rendered adequate to detect $\frac{1}{2000}$, or $\frac{1}{2500}$, of the minimum quantity required for its application at the commencement of that period.

Yet it is to be regretted that this method, in order to be successfully practised, often requires an amount of skill and address, and an apparatus of instruments and tests, which are not to be found in the possession of most persons who may be called upon to employ it. Dr. C. proved this from the writings of Christison and Orfila, and especially referred to the case of the latter, an abstract of which was recently given in this journal, under the title of Poisoning with Arsenic in Bread. "In this case," said Dr. Clendinning, "the great difficulty was to separate a minute portion of arsenic from a very large mass of extraneous material: successive sets of 'experts' failed to procure any trace of the poison; and the eminent toxicologist himself only succeeded after several days of experiment, and numerous manipulations that required consummate skill and dexterity."

The author next pointed out the various sources of fallacy attending the method of reduction in common use, and in doing so availed himself of Dr. Mitchell's observations in a late No. of the American Journal. He then came directly to the electro-chemical method which it was his wish to recommend, as being so "much simpler and easier than that just noticed, and therefore more nearly on a level with the average chemical skill to be met with in medical practitioners."

The electro-chemical method is founded on the principles laid down by Sir H. Davy in his celebrated Bakerian lecture, delivered in 1807. The best method of employing it was pointed out

by Mr. Edmund Davy, in the Philosophical Transactions for 1830; and it is on having verified the statements, and extended the application of the processes of this gentleman to experiments more properly medico-legal, that Dr. C. rests his claim for permission to bring the subject before the public.

Upon making trial of Mr. Davy's process, "I was soon surprised," said Dr. C., "at the facility with which I was enabled to procure satisfactory evidence of the presence of arsenic, even in the most complex mixtures. The mode of procedure which I have found most satisfactory is this:—A portion of the arsenicated substance is to be mixed in a platina crucible with a little muriatic acid; a piece of zinc foil or wire is then to be dipped into the mixture, and stirred about gently on the bottom for one or more minutes, when the platina will be found covered more or less extensively with a crust of metallic arsenic, of a dark grey colour, if perfectly deoxidated, but usually of various shades of grey, purple, or brown, from partial oxidation apparently of the internal surface. This metallic crust rises readily over the spirit lamp, in alliaceous vapours of white arsenic, which can easily be collected by covering the crucible with a piece of glass. The crust of oxide thus received on the lower surface of the glass, yields, though in very minute quantity, unequivocal indications of its nature, on being moistened with the ammoniated copper and silver solutions. . . .

"The following is a summary of a few recent experiments made according to this method:—1. I mixed a small quantity of white arsenic with muriatic acid in a platina capsule, applied the zinc, and after stirring it about for a few minutes, poured away the acid fluid. I then washed and wiped the capsule, and held it covered with a piece of glass for a few seconds over the spirit lamp: the arsenic quickly rose in alliaceous white vapours, and settling almost wholly on the glass, was immediately tested with the silver and copper tests. The result was the formation of yellow and green arsenites of silver and copper. 2. I mixed a few drops of an aqueous solution of arsenic with muriatic acid in a capsule, applied the zinc as before, emptied the capsule, washed it with muriatic acid, and afterwards with water, rubbed and dried it, and applied the

spirit flame. The sublimate received on glass yielded with the silver and copper tests the arsenites, as before. 3. & 4. I treated some Scheele's green not previously separated from the mother water, and some Fowler's solution in like manner, and obtained like results. 5. I boiled three grains of arsenic with half a pint or eight ounces of porter down to syrupy consistence; I then concentrated still farther a portion of this by boiling it in a platina capsule: this last I treated with muriatic acid and zinc, as above, and having emptied, washed, rubbed, and dried, as in Exp. 2, sublimed the poison on glass: the sublimate readily yielded the arsenites. 6. I boiled three grains of arsenic with half a pint or eight ounces of pea-soup, strained through a linen cloth, and evaporated to one-fourth. I concentrated still farther half an ounce of the residuum in a capsule to about a drachm. From this residue, treated with acid and zinc, I procured a crust insoluble by cold muriatic acid, and yielding over the spirit flame a garlic smell, white vapours, and a sublimate, from which I obtained the arsenites, as above. 7. I mixed about three and a half grains of arsenic with eight ounces of water, to which I added about eight ounces of beef, bread, grease, potatoes, cream cheese, and a little wine; I boiled the mixture for about half an hour, strained it through a linen cloth, and evaporated the residue to the consistence of honey: a portion of this, after having concentrated it further in a capsule, I treated with zinc and acid, and having sublimed it as before, obtained the same results as in former experiments.

"In various earlier experiments, of which I have no written memoranda, and in which I operated on milk, mock turtle soup, coffee, tea, &c. containing *but one-third* of the proportion of arsenic added to the porter, pea soup, and other mixtures just mentioned, I obtained with a little more care, indications that I considered satisfactory."

After stating the foregoing experiments, the author proceeded to point out the superior advantages of the electro-chemical method in a medico-legal point of view; its simplicity, expeditiousness, and universality of application, render it, he thinks, much superior to the reduction process of Orfila and Christison.

"However heterogeneous the mixtures on which I operated, I have always

succeeded, without any considerable delay or difficulty, provided there was not a large excess of fluid or much free nitro-muriatic acid, and provided the matter operated on was not very dense, and at the same time very sparingly imbued with poison. The first difficulty is easily removed by evaporating sufficiently; the second difficulty is removed by boiling dry, and gently torrefying, by which means the aqua regia is expelled; the third is in general readily overcome by diluting with strong muriatic acid, and boiling for some time. With these exceptions, I have found no difficulty in detecting arsenic in any instance, when present even in minute proportion. . . .

"With regard to expeditiousness, it greatly surpasses other methods: the process of concentrating by evaporation, which is often necessary, is the only considerable source of delay; but an hour or two is the most that that can possibly take. The next step, that of mechanical purification by straining, which, according to the plan of Orfila and Christison, requires 30 or 40 hours on an average, requires according to the present method but a few minutes; because, since the presence of organic matters in the strained liquor causes no additional delay or difficulty in the business of reduction, external pressure may be used to accelerate the passage of the liquor through the filter. This expedition I confess I consider of no small value. It greatly diminishes the chances of falsification, and thus favours the innocent, while it will operate against the guilty by diminishing in several ways the risk of failure of prosecutions."

The conclusion of the paper contained remarks on the universality of the method, inasmuch as it is (so far as Dr. C.'s experiments have yet gone) applicable to other metallic poisons as well as those of arsenic; and with regard to delicacy, the author added, that he procured indications of the metal from a quantity of the oxide of arsenic scarcely appreciable by his balance, though it *breaks* with $\frac{1}{1000}$ grs. when loaded with 400 grs. On this, however, he was inclined to lay no great stress, as for practical purposes, and for satisfying the ends of justice, such extreme delicacy would hardly be available; and the method was abundantly satisfactory without it.

ON FRACTURE OF THE LOWER END OF THE RADIUS,

Simulating Dislocations of the Wrist.

BY BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

ALL authors who have written on luxations of the wrist describe four species. We must go back to J. L. Petit for rational ideas regarding the pretended luxations of this nature, and the means to be adopted. Pouteau, in a memoir devoted especially to the consideration of fractures of the fore-arm in consequence of falls, has these remarkable words:—"These fractures are most frequently taken for sprains, for incomplete luxations, or for a separation of the radius and ulna at their junction near the wrist." Desault alludes to the same kind of mistake as of occasional occurrence. These observations might have excited doubts in the minds of modern surgeons, yet we find Richerand, Boyer, Samuel Cooper, &c. following the old errors, all of them having described four kinds of dislocation of the wrist, enumerated the symptoms and the methods of cure. It is, however, long since I announced in my lectures that these fractures were extremely common, and that there was not one satisfactory instance on record of this pretended luxation. I also announced that I had made dissections, and never found dislocation to be the result of a fall on the palm of the hand; but that the only ones I had found were in consequence of disease of the joint, or symptomatic of other lesions.

In considering the anatomical facts three principal articulations merit our attention: the inferior radio-cubital, the radio-carpal, and the medio-carpo-meta-carpal.

The inferior articulation of the radius and ulna presents a movement of rotation, effected by the radius being furnished with a cavity forming nearly the fourth of a circle, and the extremity of the ulna presenting a rounded surface of about half a circle. The movements of pronation and supination ought thus to be limited to a quarter of a circle; but the laxness of the membranes allows it to extend to about two-thirds of a semicircle. Adding to this what is effected at the elbow and shoulder joints, the entire rotation of the hand amounts to nearly three-fourths of a circle.

The skeleton of the radio-carpal joint is a more important object of consideration. The lower end of the radius, flattened and thickened, forms nearly two-thirds of it.

With the exception of some partial prominences which limit the grooves for the tendons, the epiphysis of the radius is situated behind, nearly on the same plane as the body of the bone, and has no remarkable prominence. Outwards, the projection extends from two to three lines, and is prolonged under the form of a pyramid with four sides; it is the styloid process, the invariable situation of which is at the extremity of the large diameter of the wrist. The anterior face is more remarkable; the epiphysis, in enlarging, is so carried forward, that it joins a transverse prominence projecting more than four lines above the level of the body of the bone. Below this is a rough surface, to which the anterior capsular ligament is attached. At the lower surface of the epiphysis is the glenoid cavity of the radius, offering an irregularly triangular form, and so constituted that, if the axis of the body of the radius is thrown perpendicularly on this cavity, it will be divided into two very unequal portions; one behind, forming scarcely one-fourth, and the other forward, equalling the other three-fourths, and which, in a perpendicular fall upon the radius, will only have, for a *point d'appui*, the portion of the epiphysis which projects before the body of the bone. This arrangement serves to account for the frequency of fractures in the neighbourhood of the articulation.

The ulna does not immediately enter into the formation of the radio-carpal articulation, but is separated from it by a triangular ligament, the summit of which being inserted into the centre of the semicircle which represents the articular surface of the ulna, is always (whatever be the position of the two bones) at an equal distance from the radius, and consequently is never stretched nor relaxed. By this simple mechanism the articular surface which receives the bones of the carpus, is never altered either in its smoothness or extent. The extremity of the ulna presents different aspects, according to the movements of the radius. When the fore-arm is in a state of forced pronation, what is called the articular portion (the prominence opposite the styloid apophysis), is turned backwards, and raises up the skin which covers it. When the fore-arm is supine, the head of the bone projects forwards; the styloid apophysis is turned entirely back. From this arrangement arise two circumstances of importance: first, that the ulnar malleolus is not always represented by the same bony projection, as the radial; and, secondly, that the great diameter of the articulation is subject to considerable variation. We see from this what degree of confidence is

to be attached to the sign mentioned by Pouteau as diagnostic of fracture of the radius, or of the ulna, viz. an increase of the diameter of the joint. In order to judge if it be really enlarged, the parts must be measured in the middle position, between pronation and supination; it is then found that a fracture, at about half an inch, or an inch above the joint, may, by the approximation of the lower fragment, separate the styloid apophyses sufficiently to effect on the great diameter of the joint an increase of two lines; but to accomplish this, it is requisite to divide the inter-articular ligament. In proportion as the fracture is higher up, the separation diminishes, so that at the lower third of the bone it does not amount to half a line.

I may here mention a very interesting point in physiognomy which has never been published before. It is, that when the diameter of the forearm near the wrist is more considerable than usual, and not dependent upon any morbid state of the parts, but upon their natural formation, you may be almost certain that such person is of weak and obtuse intellect.

M. Dupuytren having entered into some farther anatomical details, which we do not think it necessary to insert, then continued:—These preliminary observations on the anatomy of the joint require, to render the subject complete, that we should enter upon some account of the numerous instances of parallelism between the upper and lower limbs. The first remark suggested by fractures at the lower end of the radius is their analogy with those of the ankle. I had already pointed them out in my memoir on fractures of the fibula, and subsequently in a lecture published in the first volume of the *Leçons Orales*. These analogies and differences being established, let us see what happens with respect to the disposition of the bones of the forearm. Suppose that an individual in walking encounters any obstacle, the point of the foot is opposed to the ground, the movement is arrested in its direction backwards, but it is continued upwards, and the person falls on his face. The hands are instantly thrown forwards. If the joints be semiflexed the shock is lessened, but if they be extended, the bones receive the impetus in its full force. Two things may happen in this case: the individual falls on the extremity of the fingers, and these usually transmit the movement to the bones of the carpus and metacarpus, but at others the phalanges are broken. If, however, instead of falling on the fingers, the fall takes place on the wrist, the results are different: sometimes the upper part of the arm is luxated; in other

cases the elbow is pushed back; but in the majority of instances fracture of the lower end of the radius occurs because of the two bones of the forearm—one, the radius, is broad and contiguous with the bones of the carpus, while the other, the ulna, is weak, and is not articulated with the carpus. It results from this kind of fall that the shock is directed against the radius, which offers the greatest resistance: it is not astonishing, therefore, that the fall should take effect at this point.

I have said that I never saw a dislocation of the wrist, but that fractures of the radius were very common; and the following are the details, as they have been recorded at the *Hôtel Dieu*:—

In 1829, of one hundred and nine fractures, twenty-three were of the forearm—viz. sixteen of the radius, five of both bones, two of the cubitus. In 1830, of ninety-seven fractures, twenty-two were of the forearm, sixteen of the radius alone, four of both bones, two of the cubitus. This proportion has been more considerable in other years, and in those above-mentioned it is more than a fifth. M. Goyrand, of Aix, goes far beyond this. “I hesitate not to affirm (says he) that no other kind of fracture is so common as this: comparing them with all others put together, they are in the proportion of one to two.” This fracture takes place at all ages, and both sexes are equally exposed to it. With regard to the sides affected, about nine cases occur on the right arm to seven on the left. Of ninety-seven cases of fracture of the upper extremity, fifty-nine were on the right side. With regard to the causes: three fractures of the radius were produced by falls on the back of the hand, and eleven by falls on the palm. This destroys the inference of M. Cruveilhier, that fractures appear to be impossible from falls on the back of the hand.

We have seen what renders fracture of the lower end of the radius so common; we shall next glance at the seat of this lesion. It generally takes place very near the wrist joint, and in young subjects probably the epiphysis is separated. A boy, twelve years of age, fell from a height and fractured his skull, of which injury he died in three days; the epiphysis of the radius was separated, and a quantity of blood effused about the parts.

The fracture may take place transversely or obliquely, at three, or at six lines, or at an inch, from the articular surface. The consecutive displacement will resemble luxation the more, the nearer it is to the joint; and in some instances I have known a comminuted fracture, and kind of crushing of the articular portion of the radius.

For the most part fractures of the radius are simple, but sometimes they are compound; and pathological specimens have been met with, in which the former fragment has been divided vertically in two. In some rare cases the radius has been fractured, the cubitus dislocated, and protruded through the integuments. We have a case of this kind sufficiently curious to be worth relating.

CASE I.—*Double Fracture of the Radius—Dislocation of the Ulna inwards, with Rupture of the Integuments—its removal at the end of eight months—incomplete cure.*

B., a charwoman, of small stature and dry fibre, aged 62, came to the Hôtel Dieu Feb. 27, 1832. The previous evening she had made a false step, and rolled from above downwards about sixty paces. She could not tell in what manner the arm came in contact with the ground. The ulna projected through the integuments. A medical man who was called placed the hand upon a splint, and surrounded it with bandages, and next morning she came to the hospital. The left fore-arm was dislocated near the wrist; the radius was broken in two places—first, an inch above the joint, and then again an inch and a half above that. At the inner side was a longitudinal wound, along the border of the ulna, about four inches in length, and with edges as smooth as if it had been inflicted with a cutting instrument. The ulna dislocated inwards projected very considerably, more than an inch of the bone being beyond the integuments. The internal lateral ligament was broken; the muscles of the other soft parts bruised and torn. Much blood had been lost by the wound. The hand and lower part of the fore-arm were much swollen, and the bandages very tight.

On seeing the state of the parts, M. Breschet proposed amputation, but this the patient obstinately declined: he then resolved to cut off the protecting portion of the cubitus, which was immediately done in the following manner:—The hand and wrist being turned outwards, the cubitus was pulled inwards; the surgeon then detached it with a bistoury from the soft parts, which still adhered to it. About an inch and a half of the bone was then removed by the saw, carried in an oblique direction. The forearm was then enabled to be placed in its natural position, and was simply dressed and laid upon a wooden pallet.

It was not disturbed for four days, at which time suppuration was found to be established, and healthy in appearance. In three days more it was dressed again: the wound was florid, the suppuration was

rather abundant, and some portions of slough formed by the soft parts were ready to become detached. The fragments were quite moveable upon each other. Every thing went on well for some days, when on the 9th of March there appeared a swelling of the hand of cedematous character, and on examination a manifest fluctuation was perceived. On opening this about two spoonfuls of matter were evacuated, and from this time there were two wounds with pretty copious discharge; namely, that in the back of the hand, and that communicating with the fragments of the radius. March 24, the whole forearm was red, tense, and fluctuated at various points. Several openings were made, and in a few days the parts returned to nearly their natural size. Matters improved up to the 10th of April, when there was a new attack of tumefaction, and another abscess on the dorsal surface of the forearm. This was opened. Again on the 25th a similar attack took place, and yielded to similar means; and by the 10th of May there remained only a little fistulous opening on the back of the hand and on the site of the original wound. After these alternations she improved, and left the hospital August 25, the wound at the lower and inner part of the wrist not being even then quite closed. November 27, they were healed, but the use of the fore-arm was very much impaired, and had besides lost an inch and a half in length.

[M. Dupuytren then proceeded to analyze a case related by M. Cruveilhier, as one of luxation of the joint forward; but in which opinion the learned lecturer did not concur.]

The diagnosis (he continued) of fractures of the lower extremity of the radius deserves serious attention, because they have been, and often are, mistaken for dislocation. Many able practitioners fall into this error, of which the following is an example:—

A good many years ago a mason, having fallen from a great height, was brought to the Hôtel Dieu. He had several severe wounds, and among others a fracture of the cranium, accompanied by a large wound of the integuments of that part; there was at the same time a deformity of the wrist. Several surgeons were of opinion that there was luxation of the carpus backwards. M. Dupuytren maintained the contrary, and pronounced it to be a fracture of the lowest part of the fore-arm. Eventually the patient died of the wounds of the head, when the Professor's opinion proved justified.

A case, exactly similar, presented itself still more recently in an hospital in Paris. The chief surgeon (M. Marjolin) thought

he recognized a luxation of the carpus backwards. The patient died, and it turned out to be a fracture.

Among the affections which are apt to be mistaken for luxations, we may mention the following, which we have often met with. A variety in the radio-carpal articulation is sometimes observed, especially among workmen; but it has not been much attended to by practitioners. Pressmen, and artizans who have to employ traction, like that with the lever of a press, are frequently subject to it. The ligaments of the wrist become relaxed, and stretched to such a degree, as to allow of much more extensive motion than in the normal state. The carpus, in consequence, being no longer solidly attached to the forearm, yields to the action of the flexor muscles, and is drawn beneath the lower extremities of the radius and cubitus. All the signs of luxation are present, except the pain and inflammation. A deformity, more or less serious, and a weakening of the parts, are the only inconveniences which the patient feels: he can rest on them without difficulty, but a recurrence of the accident occurs at will, or during repose, by the preponderance of the muscular power in the palmar region of the forearm. Medical aid is seldom sought or required by persons so circumstanced.

When the mistake has been committed, of supposing a fracture of the lower part of the radius to be a luxation, and so has been left to itself, very awkward consequences ensue; the interosseous space disappears; the forearm, instead of presenting a broad flattened appearance in this part, has a cylindrical form; and the movements of pronation and supination are lost.

Such was the condition of a patient who came to seek relief at the Hôtel Dieu, in 1829. He had fallen on his wrist, and fractured the lower extremity of the radius, immediately above the radio-carpal articulation. Forty days had elapsed since the accident. There was swelling, deformity, the cylindrical shape just mentioned, and no possibility of pronation or supination. His cure was out of the question, as M. Dupuytren predicted.

The serious consequences, in short, of mistaken fracture, ought to excite practitioners to reduce it immediately when met with.

Mode of Reduction.—In reducing this fracture, said M. D., I draw out the limb from the body; the back of the hand is then turned upwards, and the forearm semi-flexed on the humerus. The assistant who has to effect counter extension, takes the arm by its lower part; and he who has to manage the extension, employs graduated traction on the hand, always ob-

serving to give it an inclination towards the cubital edge of the forearm. The surgeon, placed on the inner side of the limb, pushes back with both his hands the flesh on both sides of the forearm in the interosseous space; then, acting on the two fragments, he directs them one towards the other. It is a fracture readily reduced, but not always so readily kept in its reduced condition. The appareil which I use, continued M. D., is a graduated compress on the anterior surface, and another on the posterior; above, a splint, which projects a little on the hand; and after this a roller, extending from the end of the finger, covering the hand and the splint, without exercising any lateral compression on either radius or ulna. The advantages of this proceeding are obvious.

There is another important point connected with fracture of the lower extremity of the radius, and that is, the tendency which the hand and the lower fragments exhibit, to be carried beyond the radial side of the forearm. I mentioned this, said M. D., in my memoir on fracture of the fibula, both here, and in the fibula fracture, the angle constituting one of the best signs of the accident which has occurred. If this be not quickly remedied, consolidation takes place, and there is, ever after, more or less impediment in the movements of pronation and supination.

This displacement is sometimes so strongly marked, that there is a considerable projection of the cubitus inwards; that bone appears curved, and practitioners have often mistaken the injury for a luxation. About twenty years ago I first noticed this tendency, and from that time till recently I knew no better way of opposing the displacement than by the application of the ordinary appareil for forearm fractures: but I always found it insufficient. I at length hit upon the following plan: I added to the appareil just mentioned, a splint, which I have named the *cubitale*, made of a plate of iron, about an inch in breadth, and of the length of the forearm, and which at its lower extremity, and where it leaves the corresponding point of the carpus, is curved into a semicircle. In the concave of this arch, there are several buttons equidistant from each other. After the ordinary bandage has been applied, the upper extremity of the metallic bar is placed upon the internal margin of the cubitus, and between the inner side of the wrist and the convexity of the bar are laid compresses in several folds. Between the thumb and forefinger there is placed a small cushion, to the ends of which are attached two strings. These last are now brought forward, and behind the hand, into the concavity of the splint, and passed over one of the buttons in the

latter. The hand is thus drawn into its natural situation, or, if need be, beyond it, according to the button to which the strings are tied. The cubitus turned inwards, throws the two fragments of the radius out, and thus all the indications required are fulfilled, without leaving the least deformity.

CASE II.—*Fracture of the Radius; neglected for 20 days.—Rupture of the provisional Callus.—Cure complete on the 35th day.*

L., aged 69, of good constitution, came into the Hôtel Dieu on the 11th December, 1820, for a fracture of the left radius, near its lower extremity, caused by falling from a height on the palm of the hand. No medical man had been called in, and it being supposed to be a mere sprain, emollients only were applied, but they of course did no good. There was much pain in the part, and the deformity was increasing daily: had consolidation been effected under the circumstances, the movements of pronation and supination would have been inevitably lost: the swelling also was very obstinate. When the patient was seen in the hospital, the deformity was very remarkable: there was a strong abduction of the hand; a very remarkable hollow at the lower extremity of the radius; the movements extremely painful, and not performed without external aid. Upon examining the parts, M. Dupuytren immediately conceived that it was by no means impossible, notwithstanding the time that was elapsed, to give the limb its natural form. But for this purpose the provisional callus should be made to yield to the efforts used in reduction. An assistant was directed to hold the fore-arm at its upper part, for counter-extension: M. D. holding by the lower part, executed a movement with it in the contrary direction to that produced by the fracture; that is to say, he moved the parts in the sense of adduction. The callus yielded; the fragments were then thrown outwards, and the interosseous space was enlarged. The consecutive indications were managed on the preceding principles. Neither low diet, nor bleeding, were required. The bandages were renewed on the 10th day, and again on the 20th; on the 32d they were taken off altogether; and on the 35th, when the patient left the hospital, all deformity was gone, consolidation was complete, the interosseous space re-established, and the limb fitted once more to perform its natural functions.

CASE III.—*Fracture of the extremity of the Radius, mistaken for 29 days.—Completely restored.*

Jules Béchét, aged 10, fell from a height of 15 feet, on his hands, knees, and chin.

The palm of the right hand had received the greatest shock. A surgeon who was called in, having examined the wrist, pronounced it to be only a sprain; had leeches and poultices applied, but the swelling, pain, and difficulty of motion continuing, the parents of the boy became uneasy, and on the 28th day consulted M. Dupuytren. He recognized the fracture, and, notwithstanding the consolidation, ventured to express an opinion of the possibility of redressing the deformity. And the event showed the correctness of the opinion. On the 29th day, M. D. made the first attempt at reduction, and on the third day after renewed the attempt. The boy did not suffer much. The bandage was re-applied on the eighth day, and ultimately removed on the 38th. The cure was perfect.

In another case, where there was a curvature formed in the consolidation, the limb was restored to its proper shape by the 40th day.

M. Goyrand has latterly imagined that the graduated compresses ought not to come below the articulation of the wrist, but be there replaced by compresses several times folded, and so disposed as to form two cushions, the anterior of which should be fixed above the projection of the palmar region, whilst the posterior might come to any depth on the dorsal surface of the metacarpus.

The following are the conclusions which we may safely deduce from the preceding principles:—

1. Without denying the possibility of luxation of the radio-carpal articulation backwards, though I have never met with it, I would submit that it is extremely rare, and probably that it has never ensued upon a fall on the anterior part of the wrist.

2. The cases of luxation of the carpus backwards, so described by authors, were probably, in fact, fractures of the radius, situated a quarter, or half, or a whole inch from its extremity, or perhaps a simultaneous fracture of both radius and ulna.

3. That the appareil commonly employed by many surgeons in fractures of the fore-arm is highly improper, and unsuited for the indications of the injury.

4. That the tendency to displacement inwards, so commonly presented by the fragments of the radius, and whence results a corresponding inclination of the hand, requires the application of a particular agent in order to throw the fragments outwards, and to keep them in that position; and that the best agent for the purpose is the cubital splint.

5. And lastly, that when the fracture has no tendency to displacement, the simple appareil for fractures of the forearm is sufficient, without even a necessity for the use of the cubital splint.

PARLIAMENTARY ORDERS

REGARDING THE COLLEGES OF PHYSICIANS AND SURGEONS, AND SOCIETY OF APOTHECARIES.

House of Commons, Die Junii 22, 1833.

PHYSICIANS' COLLEGE.

"COPY ordered of the regulations or bye-laws under which Graduates in Physic have been admitted as Fellows of the Royal College of Physicians of London since the year 1771."

"Accounts of the number of persons who have been admitted as Fellows of the Royal College of Physicians in each year since 1771, distinguishing the number admitted under each bye-law, and also the number rejected."

"Of the number of persons who have been admitted as Licentiates of the Royal College of Physicians of London from 1st January 1823 to 31st December 1832."

"Of the money which has been received by the Royal College of Physicians, from persons admitted as Licentiates from 1st January 1823 to 31st December 1832, and of the manner in which it has been appropriated."

SURGEONS.

"Accounts ordered of the number of persons who have obtained diplomas from the Royal Colleges of Surgeons of London, Edinburgh, and Dublin, in each year, from 1st January 1823 to 31st December 1832."

College of Surgeons (London).—Address for "Account of the money which has been received by the Royal College of Surgeons of London, for Diplomas granted to persons who have been examined, from 1st January 1823 to 31st December 1832, and of the manner in which it has been appropriated."—(*Mr. Warburton.*)

College of Surgeons (Dublin).—Address for "Account of the money which has been received by the Royal College of Surgeons of Dublin, for Diplomas granted to persons who have been examined, from 1st January 1823 to 31st December 1832, and of the manner in which it has been appropriated."—(*Mr. Warburton.*)

College of Surgeons (Edinburgh).—Address for "Account of the money which has been received by the Royal College of Surgeons of Edinburgh, for Diplomas granted to persons who have been examined, from 1st January 1823 to 31st December 1832, and of the manner in which it has been appropriated."—(*Mr. Warburton.*)

APOTHECARIES.

Apothecaries' Bill.—Order for further consideration of Report read; Bill re-

committed to the Lord Advocate, Mr. Lamb, Colonel Wood, Mr. Abercromby, Sir John Hay, Mr. Francis Kennedy, Sir Robert Inglis, Mr. Warburton, Mr. Hawes, Mr. Hume, Mr. Shaw, Mr. Ewing, Mr. Romilly, Mr. James Oswald, Mr. Goulburn, Mr. Frankland Lewis, Mr. Thomas Gladstone, Mr. Serjeant Perrin, Mr. Brodie, Mr. Ord, Mr. Edward Stanley, Mr. Hughes Hughes, Dr. Baldwin, Mr. Hurst:—Petitions referred.

PROVINCIAL MEDICAL ASSOCIATION.

THE annual meeting is to take place on the 19th of July, and to be held in the Infirmary at Bristol.

PHRENOLOGY.

On the *first of April* last, a Mr. Burke announced to the Phrenological Society of London that he had discovered sixty-three new organs in the head! This makes above a *hundred organs* of the head now known to phrenologists,—the fruits of their peculiar genius for discovery.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE ABDOMEN.
—

ACUTE PERITONITIS.

THE first disease of which I shall speak, after passing the diaphragm, is inflammation of the peritonæum—*peritonitis*.

Symptoms.—This disease is, of course, attended by pyrexia—general feverishness. Although the whole body is hot, yet generally the abdomen is hotter than other parts. The pulse is, for the most part, rather small; of course it is quick; sometimes it is wiry, sometimes it is hard, and sometimes it is soft. There is no invariable pulse in peritonitis, with the exception that it is always quick; more frequently it is small than full, and perhaps more frequently rather hard than soft. There is a great variety as to the appearance of the tongue: sometimes it is really pretty clean, at the utmost only whitish; sometimes it is covered with a thick creamy mucus; sometimes it is rather dry. You have no very great index either in the appearance of the tongue, or the character of the pulse; but the abdomen is always very tender on pressure, and the tenderness is too general for one to suppose that any particular organ is inflamed. One of the modes of distinguishing peritonitis from inflammation of a particular organ is, by observing that the tenderness of the abdomen is not in the seat of any particular organ whatever, but is more or less general. As the peritonæum stretches all over the abdomen, and a great proportion of it is usually inflamed,

the patient is most frequently easier on his back than in any other position; and sometimes, to obtain all the ease possible, the patient lies with his knees spontaneously raised. In general, patients cannot sit up, on account of the abdominal viscera gravitating so much as to produce painful distention, and therefore they are easiest in a lying posture. Besides the tenderness, there is very frequently pricking pains of the abdomen, as if needles were running into different parts, and occasionally there is a sharp cutting pain. The abdomen is usually very tense. As it is a mere membrane that is inflamed, the bowels are in general not particularly disturbed; they are regular, or at the utmost they are only slightly confined, and are easily opened: there is no obstinate constipation.

Although the inflammation is generally very universal, yet of course it may rage more severely at one spot than at another, and consequently there is more pain at one part than at another; and if that part be situated over any particular organ, then you have the function of that organ more or less disturbed. If, for example, at any particular period of the disease the membrane covering the stomach is inflamed, you have vomiting induced; if it be the portion which covers the bladder—and which is only partial, as you know—then there may be very great irritation of the urinary organs. In the former case you have vomiting; in the latter, stranguary.

Prognosis and Diagnosis.—As the inflammation spreads, it attacks one part after another. It is the peritonæum at large that is inflamed, and therefore the tenderness is general and the pain diffused, and any disturbance of function that exists in the abdominal viscera is trifling in proportion to the general pain and uneasiness. It is in this way that you distinguish it from inflammation of any particular organ.

Duration.—This disease, when acute, may last about a week before it proves

fatal; but if it remits, it may of course last much longer.

Morbid Appearances.—After death, the appearances found are nothing but those which are usual in inflammation of a serous membrane; for example, a quantity of serum of a whey colour, more or less turbid, with flakes of fibrin. It is rare to find the serum bloody. The fibrin is frequently effused in a gelatinous form both in the parietal and visceral portions, and perhaps adhesions are thrown out, so that there are bands. Now and then the secretions resembles pus, and now and then it is really pus. As to the redness of the peritoneum, that may be either in little stars, a collection of red points, or it may be diffused in patches. The peritoneum, like most other serous membranes, becomes rather thicker than usual: it is not so translucent as in health, and now and then it is exceedingly pulpy. When the peritoneum covering the alimentary canal is inflamed, the redness will sometimes spread inwards, even to the villous coat; but it is very rare to find inflammation of the parietal portion spread outwards, towards the abdominal muscles. When the portion covering any particular organ is inflamed, you may find the organ itself affected, as, for example, the omentum or the mesentery, so that you may have *omentitis*, or *mesenteritis*, or any other *itis* you may choose to manufacture out of the name of the organ, and the termination *itis* added to it.

Puerperal Peritonitis.—This disease very often occurs in a puerperal state, and by some it is thought occasionally to be contagious. It is called, when occurring in that state, *puerperal fever*. Sometimes it will take place immediately after delivery, and sometimes many days afterwards, whether the patient is sickly or not; and, on the other hand, it will sometimes take place during the latter period of pregnancy. Whether it is a contagious fever or not, it certainly is very often epidemic, and one might say endemic, for frequently this disease, puerperal peritonitis, prevails to a great extent at a particular period, and sometimes it prevails only in particular districts.

Causes.—Peritonitis is very frequently a cause of death in cancer of the womb, or various other diseases of the uterus or ovaries. Whenever cancerous or other ulceration occurs in these parts, and exists for some time, the peritoneum around the ulceration comes to be inflamed, so that peritonitis is a common termination of organic diseases of these parts.

Peritonitis sometimes occurs also from ulceration, after a rupture of the stomach or intestines. Of course you are aware that it sometimes takes place from a

hernia, either from the operation for it or the hernia itself, from an operation for stone, from paracentesis abdominis, and so on. It will arise from any wound, or from a mechanical injury of any sort inflicted on the abdomen. It is frequently consequent upon the application of cold, and especially cold and moisture applied when the body is overheated, just the same as any other inflammation.

Treatment.—The treatment of the disease is easy enough. It consists of general bleeding followed by an abundance of local bleeding, by means of leeches, (cupping would produce great pain,) a rapid affluence of the mouth by mercury, and keeping the bowels well purged the whole time. Some prefer fomentations and others blisters; perhaps, it is not a matter of importance which you apply; but if you have bled as much as you dare, and still want to do more, then blisters will be the great point of treatment. Some have recommended the external application of cold to the abdomen in such a case, but I have never employed it.

In that form of the disease which occurs in connexion with pregnancy or the puerperal state, it is found that a great variety of treatment is necessary. You may have cases where there is active inflammation demanding vigorous antiphlogistic treatment, such as I have now mentioned; whereas, in others, the very utmost that can be borne is the application of leeches. Patients are seized with more or less pain in the abdomen, but you find that the pulse is feeble; and if you bleed them, they will certainly sink so much the sooner; and, therefore, all you can do is to apply a few leeches, to give a moderate quantity of mercury, and exhibit opium freely. So slight is the inflammation in some of these cases, and so great the loss of power, that after death the peritoneum is not found red, but rather pale, and it will have lying upon it a very soft lymph, shewing that there was an inflammatory state, but that it was attended with extreme weakness. Where you find that the pulse is feeble, and the patient's countenance expressive of great debility, opium is by far more suitable than bleeding; but if the tenderness seem to indicate bleeding, a few leeches would be all that was proper. In such a case as this, purging even has been found to be too severe a measure; but there can be no objection to a moderate quantity of mercury, but such a preparation as will not produce an affection of the bowels—for instance, hydrarg. c. creta. The application, too, of warmth and moisture will be found very serviceable. Dr. Goode, who has well treated on the subject, as far as I can observe, strongly recommends the application of bran, moistened with hot water,

and placed between two pieces of linen. A bran poultice appears to afford very great relief.

You see, therefore, that the peritoneum may occasionally be in an inflammatory state, but attended with such extreme weakness that the common remedies for inflammation can hardly be put into practice. This is somewhat analogous to what I mentioned respecting hydrocephalus—that occasionally children have all the marks of that complaint, and yet no signs of inflammation are observed after death. In the case, however, before us, the membrane is inflamed, but the debility is out of all proportion to the inflammation. You perceive that the treatment of peritonitis connected with the puerperal state, especially after delivery, requires to be much varied.

CHRONIC PERITONITIS.

Symptoms.—Inflammation of the peritoneum is very frequently a chronic affection, and in that case there is pain on pressure—that is to say, there is tenderness, and likewise pricking pain. There is almost always a feeling of tension, and sometimes that is more complained of than the pain itself, but there is not necessarily any tension to be discovered, for sometimes the integuments are quite flexible. Of course there is pyrexia. The pulse is constantly quick; there is more or less thirst; the skin is generally more or less dry; the tongue is foul, and either white or yellow towards the back; the breath, too, in this disease is very frequently foetid; the face sometimes assumes a doughy aspect; the bowels generally are torpid, and frequently there is ascites, from the chronic inflammation of the membrane causing an excessive secretion. As the inflammation is of a chronic character, of course you may presume that the body wastes. The internal functions are very much deranged. The stools are very copious, and generally of a white-brownish colour, not being so fully impregnated with bile as they should be; and the mesenteric glands are frequently diseased. In fact, for the most part, when chronic peritonitis occurs in young persons it is a scrofulous disease, and is connected with more or less affection of the mesenteric glands.

Morbid Appearances.—After death you may find excessive redness and thickness of the membrane, and an effusion of serum and fibrin.

Treatment.—The treatment of the disease consists in the frequent application of leeches; the frequent use of the warm bath, general or partial; warm applications, such as the bran-poultice I mentioned, applied constantly day and night, or, as some have recommended, cold applica-

tion, frequent blisters, and a regular purging with calomel. The contents of the intestines are very abundant. Of course the diet should be mild. If there be no very great excitement, you may, after the disease has lasted some time, try mild tonics—the mildest form of iron; but during the greater period of the disease, antiphlogistic measures, mildly carried on, is the preferable mode of treatment.

Scrofulous Enlargement of the Mesenteric Glands.—If with this disease the mesenteric glands are enlarged, (or if, indeed, they are enlarged without this affection) you may or you may not, have a tumor. The mesenteric glands are frequently much diseased without producing a tumor, yet they are sometimes so diseased that you find a general hardening of the abdomen. When peritonitis exists, in the greater number of cases you can only infer disease of the mesenteric glands from the scrofulous look of the patient, from his wasting away, and from there being something more than chronic inflammation of the peritoneum can produce. When there is tumefaction from disease of the mesenteric glands, a great deal of it is frequently flatulence, so that if you strike with the fingers, you have a very considerable sound. Sometimes tubercular substance is deposited in the peritoneum itself, so that besides chronic peritonitis, you have scrofula of the peritoneum. It is by no means easy to make out the exact nature of such a case as this. It is pretty clear that there is peritonitis, and that there is likewise scrofula; but whether there are tumors or not, or whether the disease affects the mesenteric glands, or the peritoneum itself, is not always an easy matter to decide, nor is it of any consequence.

Symptoms.—Occasionally the mesenteric glands acquire a very large size, and before that there is a great sense of dragging in some particular direction. In those cases which are very bad, and where there is scrofula in the abdomen as well, there is great emaciation; sallowness of the complexion, sometimes a sort of marble white; a hectic flush on the cheek, at any rate at certain parts of the day; and the eyes look clear and glazed. Occasionally, in the course of the day, there is deep lancinating pain in some parts of the abdomen. The stools are generally abundant, foul, frothy, and imperfectly tinged with bile. Occasionally there is great disturbance of the stomach, so that patients complain of a burning sensation in that organ. The lips frequently swell, are of a deep red colour, and crack, from ulceration in the corners. Of course there is feverishness. Although the pulse is constantly quick, yet

there are exacerbations. When the patient does not sweat on falling asleep, the skin is frequently quite dry. The emaciation in these cases is often extreme, and you frequently see the ends of the fingers enlarged, exactly as in phthisis.

These are the general symptoms of serofula of the mesenteric glands and of peritonitis. The symptoms are always much more severe, and the emaciation is greater than in simple inflammation of the peritoneum, but still it is often difficult to say whether the latter affection exists alone, or whether the two complaints are united. It is only by finding that the disease is inveterate, that it will not give way to common antiphlogistic measures, that you at last begin to suspect that there must be something more than inflammation.

Occasionally it is not so much the mesenteric as the lymphatic glands that are diseased, the glands of the loins particularly.

All these affections occur more frequently in children than adults, but you see them occasionally in the latter.

If the mass of tubercular substance be very great, it may produce peculiar effects, by its pressure on various parts. From pressure on the ureters, you may have more or less suppression of urine; by pressure on the gall ducts, you may have jaundice; and by pressure on the pylorus, you may have vomiting. Some have supposed that when the mesenteric glands are enlarged, the emaciation is the consequence of the chyle being interrupted in its course; but even if the chyle be not obstructed, the serofulous disease is sufficient to account for the wasting of the body; in fact, some experimentors say that they have always found an injection pass freely through the absorbent glands, although they were enlarged in various degrees. Many have asserted this.

Treatment.—When you see a disease of this description—when you suspect that, besides chronic inflammation, there must be something more, from the disease not giving way to ordinary treatment, to the application of moisture, warmth, and steady purging, or moderate purging, local bleeding, and all these things, it may be right to exhibit iodine in its various forms; and if you can discover a tumor in any part, or any general hardness of the abdomen, so as to make it probable that the mesenteric glands are enlarged, it may be given from the first. We should also rub in iodine in the form of hydriodate of potass, as the patient can bear it; but there is frequently too much pain for it to be borne at all. The hydriodate of potass will often be borne when the iodine itself cannot. But these are, of course,

very unsatisfactory cases to treat, and frequently all that we can do is to send people from the unhealthy situation in which they may reside, to the fresh air. The havoc which is found in these cases is sometimes dreadful. You may see the whole of the intestines glued together. Sometimes you will see ulceration of the peritoneum itself, the intestines being sound within. Occasionally the ulceration makes the peritoneum quite thin; it even ulcerates through, and then you find ulceration of the intestines, and chronic inflammation of the mucous membrane of the intestines and the lacteal glands, and frequently the lumbar and dorsal glands are all in a state of enlargement and suppuration; so that there is extreme suffering and the most decided hectic before death, and after it you certainly have the most frightful spectacle that can be seen in morbid anatomy. This is entirely a serofulous affection.

ASCITES.

Sometimes, although the chronic inflammation of the peritoneum is very inconsiderable, yet the effusion is exceedingly great; and sometimes indeed there is scarcely any mark of inflammation to be found, but you have a structural change of the peritoneum, and a great deposition of water. The peritoneum becomes thick, and assumes a satin whiteness; in fact, it looks like a piece of satin ribbon, so that you may doubt whether you can call it inflammation or not, but it is of an inflammatory nature. When this effusion is very considerable, we call the disease *ascites*.

Causes.—When ascites is not the result of acute or decided inflammation, you will find in most cases that there are marks of structural change; and some ascribe it to disease of the liver—so frequently is that organ affected at the same time. Where, however, the peritoneum is diseased, you will find that portion covering the liver very thick, quite white, and opaque; and I do not believe that ascites arises from disease of the liver, but from a structural change in the peritoneum itself. Some ascribe it to an obstruction in the liver or spleen. An obstruction in those organs may exist; but if it arose from that source, it is very odd that we do not find all the veins enlarged, very odd that there is no effusion into the intestines, a varicose state of all the veins, and things of that description. I have seldom opened a case of ascites in which the liver was not diseased in some part or other.

Symptoms.—Dropsy of the peritoneum is characterized by a fluctuating and elastic equable tumefaction of the abdomen. At first it only inconveniences a patient when

he is sitting upright, and fluctuation is discovered only at a certain point; but as the disease extends the tumefaction becomes universal.

The best mode of discovering the fluctuation is to place the hand against one part of the abdomen, and then give a gentle tap with the fingers on another. Occasionally the integuments or the peritoneum are very much thickened, and it is necessary to give a good sharp tap; but for the most part a very gentle tap will lead you to feel the fluctuation. You will sometimes not find the fluctuation throughout, and occasionally the peritoneum differs in thickness at various parts, so that it is necessary to tap from above downwards, and in various ways.

There is in general, of course, as in most other dropsies, very little urine; but however much the abdomen may be distended, there is generally little dyspnœa so long as the chest remains free: so long as there is not disease of the heart, or pleuritis, or bronchitis, it is surprising how well patients will breathe with a very large abdomen.

The tumefaction begins of course in the lowest part, and gradually ascends till the whole abdomen is distended with it.

Prognosis.—If the disease be the mere effect of acute inflammation, subdue that, and the dropsy will cease; but when it does not arise from that source, or is not the result of any discoverable inflammation, the prognosis is generally bad, and more especially if you can discover disease of any of the abdominal viscera.

Progress.—This affection after a time is followed by œdema of the legs; but sometimes the latter begins first, and the ascites is nothing more than the result of a general tendency of the cellular membrane of the body, and the serous membranes, to secrete fluid. But where there is not this general disposition to dropsy, and its occurrence in the abdomen is a local disease, the legs swell last, and frequently this does not take place for a length of time. You recollect that Shakspeare describes Falstaff as having a decrease of the legs and an increase of the belly.

Qualities of the fluid.—The fluid that you find after death, or which you let out, is generally yellow and glutinous, and the longer the disease lasts, and the more frequent the patient is attacked, the darker it generally becomes, and the worse becomes the case itself, because the peritoneum falls more or less into disease, and perhaps becomes quite soft.

Treatment.—The treatment of the disease must depend in the first place as to whether there is any inflammation or not. If you discover inflammation, generally speak-

ing, you have merely to treat that; but if you find no inflammation at all, simply a swelling of the abdomen, you will frequently get rid of it by purging the patient briskly with elaterium, or any hydragogue purgative, such as jalap or cream of tartar; but better than all other things is elaterium, and patients will take this for a considerable time, every day, or every other day. It is necessary, however, to begin the dose very carefully, for one person will not bear above a quarter of a grain, whereas I have given others five or six grains. Much depends upon the preparation: nothing is more adulterated than elaterium. Some houses prepare it very carefully, and some very badly; but when you have a fairish preparation, you should give a quarter of a grain, and ascertain how far it and the person to whom you give it agree together. If you give a grain at first, it may produce such violent vomiting and purging as to cause great distress. Some patients will bear the dose increased to five grains, but generally the average quantity is from half a grain to a grain and a half. While you exhibit this every day, or every other day, it will be good practice to support the patient with wine, so that while you drain him well you make him some sort of amends for it. It is astonishing how much fluid may be got away; and while there is no rule for the dose, yet the object is to discharge as much liquid from the alimentary canal as possible, according to the patient's strength.

Purgatives are certainly among the best means you can employ: neither leeches nor the application of blisters do much good. If you can find that there is organic disease of any sort, you may give mercury, iodine, and things of that description; but frequently with all these you do not succeed, and you are obliged to tap the patient. I do not know that there is any harm in tapping early; but, on the contrary, it may be of great use in preventing the parts from becoming so stretched that they will not contract again. Others have thought the same, but I have not a series of cases treated on each plan. It is a fact with respect to dropsy of the ovaries, that the more you tap, the more harm you do. The sooner you tap the patient, the sooner must she be tapped again. There is no doubt but that in ovarian dropsy, the greater the length of time you can postpone the operation, the longer you may still put it off; but this is not the case in dropsy of the peritoneum.

If you choose to treat the disease with diuretics, which is frequently a good practice, squills, digitalis, and mercury, answer exceedingly well. This is not so certain a practice as treating the case by

hydragogues, which are also diuretics, but if you adopt it you will frequently find that the kidneys will not act, and yet if you tap the patient they will act directly. It is common, when the abdomen is in a state of great distention, for the kidneys to refuse to secrete, but if you take off the tension the patient will make a great quantity of water. You will observe this whether patients are taking diuretics or not. It is always an useful plan, when the water is diminishing, to have the abdomen well bandaged, or to have a thin belt, producing equal pressure throughout. You will find this apparently of very great use.

As to the mode of operating, and the part to be selected for the purpose, I need not say any thing on that subject. It would be well, however, before you propose the operation to a surgeon, carefully to ascertain whether the disease exists—to ascertain, not merely that there is fluctuation, but fluctuation from a collection of water in the peritoneum; because the urinary bladder will occasionally become enormously distended. I have seen it so distended that the person has been supposed to have ascites, but on drawing off the urine the ascites entirely disappeared.

This disease sometimes co-exists with pregnancy, and pregnant women have been tapped for ascites with success. Sometimes it will co-exist with a diseased ovary. I have known instances where the ovary was as large as a child's head, and, in addition to that, there was ascites all around it.

Organic Diseases of the Peritoneum.

The peritoneum is subject to some other diseases—such as scirrhus tumors, subject to become cartilaginous, to become bony, to have fatty tumors deposited in it, and hydatids; and the same applies to the omentum.

The lymphatic glands within the abdomen, besides being subject to the disease I have mentioned (scrofula), are sometimes found after death to become indurated, almost changed to cartilage, and to have suppurated, independently of all scrofula—to have pus collected in them, in a small quantity, or in drops. These glands are also subject to melanosis—subject to scirrhus, and to the formation of earthy connexions; and so likewise are the mesenteric glands, but you cannot make out the real nature of the affection till after death. When the inner surface of the intestines is much diseased, you are almost sure to find the mesenteric glands also affected. When there is scirrhus, or cancer of the intestines, all the neighbouring glands, the lacteals and the absorbents,

are commonly enlarged, and are labouring under the same disease; but you cannot discover this during life, except by chance some particular tumor is produced.

The peritoneum is likewise subject to the formation of cysts; at least the sub-cellular membrane. Occasionally cysts are found in other organs, which project into the peritoneum: sometimes the ovaries will become dropsical, cysts are formed in them: occasionally large cysts are attached to the concave surface of the liver, sometimes to the centre, and in other instances to the side; so that, besides general dropsy of the peritoneum, you frequently have large serous cysts. In these cases the tumor is not general, but local—does not occur at the lower part particularly, but may take place any where in the abdominal region. It usually occurs at one side, in the first instance, and arises from the ovaria. You will find that the fluctuation is local. Though the tumor most frequently arises from the ovaria, yet I have seen a large cyst at the epigastrium attached to the liver. Now and then there are small cysts attached to the spleen, and at last the tumor will become so excessively large that it is impossible to say whether there is ascites or not; the whole peritoneum will become filled. So again, with respect to the ovaries; you may not be able to say whether there is ovarian dropsy or not.

OFARIAN DROPSY.

It is surprising to see how much water is sometimes collected in cases of ovarian dropsy. I once saw an old woman who had had the disease many years, and never would be tapped. She was an immense size, and at last grew so big that a certain quantity of water was let out, and we found that it amounted to eighty-four pints. The diaphragm had been pushed up to the fourth rib, the chest was exceedingly small, but the size of the abdomen was immense. That, however, was nothing to what other people have seen. Mr. Chevalier says that he once saw one hundred and thirty-six pints removed, all of which must have existed at once. You will find the case in the third volume of the *Medico-Chirurgical Transactions*. It was drawn off at three or four times. The health in these instances is not affected, as in dropsy of the peritoneum, so that a woman at Paris lived to be tapped three hundred times. Another woman was tapped one hundred and fifty-four times, and in the course of this she had three children, and was tapped two or three times during each pregnancy, so that she lost no time, but

went on bearing children and bearing water. At least twenty pints were removed at each time, and she was tapped at various periods during twenty years. There is another case where six thousand six hundred and thirty-one pints were taken away. It was not all removed at once, but drawn off at eighty operations, performed in the course of twenty-five years—women sometimes live so long in this affection. I suppose they kept a very accurate account. In one year this woman had four hundred and ninety-five pints taken away. The case is mentioned by Dr. Mortimer, in the *Philosophical Transactions*. There is an account, by a celebrated French surgeon, of a case where four hundred and twenty-seven pints were taken away in ten months. A case is mentioned by Mr. Carruthers, in his work on *Inflammation*, where a woman was tapped nineteen times in three years. A German author mentions an instance where a person was tapped one hundred and forty-three times. Only two years ago, an advertisement appeared of a woman who wished people to go and see her, (and pay for it, I presume) who stated that she had been tapped one hundred and twelve times, and had had two thousand eight hundred and eighty-eight pints taken away from her. She came from Chepstow. I had not time to see her, but she had the certificate of a medical man, stating that he had performed one hundred and twelve operations, and had removed two thousand eight hundred and eighty-eight pints. Whether the case is true or not is of no consequence, because no doubt great quantities have been taken away. It is no matter whether exactly six thousand six hundred and thirty-one pints were drawn off; five thousand will do very well to illustrate the fact that people in this disease will live very long, suffer an immense secretion of water, and bear the operation of tapping in this extraordinary form.

Quality of the Fluid.—The fluid in ovarian dropsy is frequently exceedingly greasy, so that you will find on the surface a quantity of iridescent, or at least whitish shining substance, which, if rubbed in the fingers, will form an unctuous mass. I have collected it, and found that it would melt and burn like any waxy matter; it emits a bright flame, and is insoluble in water. Dr. Bostock mentions in the 15th vol. of the *Medico Chirurgical Transactions*, that in a case of very old hydrocele he found the serum mixed with a portion of this unctuous substance. He conceives it to result from a change which the fluid has undergone subsequently to its original deposition: in order, however, for that to have taken place, it must have been of very long standing. He found it to be analogous

to that greasy unctuous matter which is called *adipocire*. He terms it *albumino-serous matter*, and says it is distinct from *cholesterine*: it is not the same as that which is found in the liver, the urine, and certain biliary calculi, though it is of an analogous nature. Something like this has sometimes been found in the thyroid gland, and in the fluid of various tumors. You will find some chemical observations upon it in the volume to which I have referred.

Dropsy of the Fallopian Tubes.—Occasionally you will have what perhaps may be, and sometimes is, called encysted dropsy of the abdomen, arising from a fallopian tube being closed at each end, and a great quantity of fluid being amassed within.

Treatment.—Now in dropsy of the ovary I should certainly make it a rule to defer the operation of tapping as long as possible: first, for the reason I mentioned before, that it is a fact, that when you have once tapped a patient, she soon requires to be tapped again, (and this is a common opinion among the vulgar;) and, secondly, because, although in an early period of the disease, there may be many cysts, yet in general they ultimately open into each other, so that you have only one great cavity. Hence, if you tap early, you most probably draw off only a portion of the fluid by the operation, the cysts being distinct, not freely in contact with each other.

In these cases the only remedies that I am aware are of any use are iodine, and sometimes mercury. Indeed, the best practice in cases of encysted dropsy of the ovaria is to support the patient's strength, to put off tapping as long as you can, and give no medicine whatever except it be iodine. It is in vain by diuretics to attempt to excite absorption, and by purging you will only nauseate the stomach, and take away the appetite.

I have seen cases of encysted dropsy of other parts of the abdomen apparently yield to the free exhibition of iodine internally, and its application externally, and I have seen it succeed partially in dropsy of the ovary. I have fancied that the power of these remedies has been increased in a trifling degree by combining them with mercury.

Very often when an ovary is enlarged there is no fluctuation for a length of time to be found; the walls are solid, solid substance is deposited, and it is not till the fluid has accumulated to a considerable extent that you can discover fluctuation. Encysted tumors of the abdomen, especially in young women, are partly solid and partly fluid; and occasionally, if you squeeze the part, you find small moveable tumors, having portions of cartilage sometimes deposited, and in some cases you

find hydatids within. I had a case in 1828 in which there was a tumor of this description, and which I concluded was a tumor of the ovary. Fluctuation was not very apparent, but still there was fluctuation. I was giving this patient considerable doses of calomel on account of there being a large quantity of solid substance, *apparently* (I fancied there might be, as well as a collection of fluid) of very great hardness, when she was seized with violent vomiting and purging. Whether this arose from the calomel I will not say, but she had been taking it for some little time, and with the vomiting and purging there was intense pain. In the course of one night the tumor entirely disappeared, after having resisted every other means for some months. It might be that the tumor in this case had burst into the peritoneum, that the fluid had been quickly sucked up by the absorbents of the peritoneum, and as quickly secreted by the vessels of the kidney; or it might be that violent purging being set up, a great discharge took place from the intestines, and the absorbents went to work, and reduced the tumor. However that may be, after a time the fluid re-accumulated, and the tumor became as large as ever, and that after no very great lapse of time. One would hardly suppose that the absorbents within the tumor were sufficient to produce such rapid absorption: it is more likely that the tumor had burst at some other part. It would appear, at least we are told, that occasionally the fluid has been discharged by the vagina—that tumors of this kind have ruptured into the peritoneum, and the fimbriated extremities of the fallopian tubes have set to work, pumped away, and poured the fluid into the uterus, and thus it has been discharged. But there are several cases on record of women falling down with ovarian dropsy, and beginning very soon to discharge a quantity of water from the vagina till the swelling had disappeared. It is difficult sometimes in these cases to know whether the water comes from the vagina or the urethra; if it comes from the former, we must suppose that the tumor had ruptured, and that the fallopian tubes had pumped up the fluid; whereas, if it comes from the latter, we must suppose that the vessels of the peritoneum have sucked it up, and then it has been re secreted by the kidney.

TYMPANITIS.

Occasionally air is collected in the peritoneum, and this is one of the diseases called *tympanitis*. Sometimes the intestines are exceedingly distended with air, so that the person becomes very large, and the tumor gives rise to a sound like a

drum, whence it is called *tympanitis*. But more properly speaking, *tympanitis* is a great collection of air in the peritoneum; and I believe this usually takes place from an aperture existing in the intestines, so that it escapes.

DISEASES OF THE PANCREAS.

Having said thus much on diseases of the peritoneum, I shall speak of those of particular organs, and first of all of diseases of the pancreas.

The diseases of the pancreas with which we have to do are all structural. We do not know what (if there be any) functional disease to which it is liable, unless it be the formation of stone. One does not know what office the pancreas performs out of order or in order: we know nothing about it. No one would refer a symptom that he has to mere functional disease of the pancreas. It is very seldom that it is the subject of acute inflammation; I never met with such a case; but now and then it is diseased in a chronic manner, especially when there is disease of a neighbouring organ.

Diagnosis.—The diagnosis of structural disease of the pancreas must be exceedingly difficult. Dr. Pemberton, in his work on Diseases of the Abdominal Viscera, says there is deep-seated pain in the epigastric region, especially if one hand be placed at the back and the other on the stomach. However, the pain may not be felt, or you may have pain there from an affection of the stomach, so that very little, I should conceive, is to be learned from that. He says there is more or less sickness, gastrodynia, and emaciation, but I should think that in general it must be a mere guess, even if the person is right, when he pronounces that the patient is labouring under diseases of the pancreas.

The most common affection of this organ is either common induration, or that particular disease called *scirrhus*. Dr. Baillie says that he once saw an abscess in it, and now and then common ulceration is seen. It is said sometimes to be ossified, sometimes to have hydatids, sometimes it is wasted, and sometimes it is very large; but for the most part this organ is not found diseased in dead bodies, and whenever it is, I believe the disease has evidently been of a chronic form.

Pancreatic Calculi.—Now and then a calculus exists in the ducts. I opened a patient not long ago, (I forget what was the matter with him) and was surprised to find calculi in the pancreatic duct. The appearance was exactly the same as that given in one of Dr. Baillie's engravings. You know that the duct of the pancreas runs the whole length of the

organ; that it is fine at one end and large at the other, and that the ramifications of it altogether look like a feather. I believe these calculi are always homogeneous, and there must have been at least a hundred in the case that I opened. The duct represented in Dr. Baillie's engraving has attained an enormous size. These calculi were analyzed by Dr. Wollaston, and found to consist of carbonate of lime in the human subject, and phosphate of lime in the ox. But these topics are more the subject of morbid anatomy than of the practice of medicine.

DISEASES OF THE SPLEEN.

The next disease of which I will speak is an affection of the spleen. We know nothing of disordered function of the spleen any more than of disordered function of the pancreas, but structural diseases of the organ, and inflammation of it, are sometimes exceedingly evident; but, like the pancreas, it is very rarely affected with acute inflammation or suppuration. Now and then, in peritonitis, that portion of the membrane covering the spleen is inflamed; but, to speak more particularly of the substance of the spleen itself, inflammation and suppuration are exceedingly rare.

Chronic Splenitis.—When it is the subject of chronic inflammation, there is pain in that quarter—pain far back on the left side, higher than the kidney, but there are no symptoms of chronic inflammation of the kidney—such as a retraction of the testicle, pain down the thigh, pain in the testicle, and an unnatural desire to make water. There is an absence of the symptoms of inflammation of the kidney.

Hypertrophy of the Spleen.—It is not uncommon to see this organ enlarged after ague. You will recollect my stating that this disease is called ague-cake by the common people, but technically it is termed hypertrophy of the spleen. When it is in this state it is generally harder than natural. The size that the spleen will attain is very considerable. I have seen it reaching the pelvis, and extending from the navel towards the other side.

Diagnosis—Size the Tumor may attain.—You will easily distinguish between an enlargement of this organ and an enlargement of the liver, by this circumstance—that, on applying the fingers, you find the edge is vertical; whereas, in enlargement of the liver, you find that the edge of the tumor is horizontal. It has sometimes weighed twelve pounds. Hoffman mentions finding one that weighed fifteen

pounds; and Morgagni, on second-hand information, mentions a case where the tumor weighed thirty-five pounds.

Liability of Children to it.—This disease will occur in children, and I have frequently seen it in infants.

Causes.—It generally arises after ague, or after the patient has been exposed to malaria. I met with a singular instance of this enlargement about a year ago. A woman had two children, and she herself had had ague, but they never had. I think she had lived in an aguish part of the country before they were born. One of the children had enlargement and induration of the spleen, and died. After a time, the same disease began in another child, and I believe it is going on now; and I have no doubt but that it will kill it. On opening the body of the first, we found the spleen enlarged and very hard, but otherwise the structure appeared healthy: there was no unnatural appearance in it.

Constitutional Effects.—Patients in this disease generally are exceedingly pale; the blood is not proper in quality, if it be in quantity—it is deficient in fibrin, and deficient likewise in red particles. The wasting of the body is not in proportion to the paleness; the patient's bulk remains pretty good for a long time, although he will become blanched—in a state of anæmia. Now and then there is a little ascites; the peritoneum covering the spleen becomes affected like the rest of the membrane, and produces a larger secretion than before.

Diagnosis.—The diagnosis is very easy long before the spleen has attained to a large size.

Treatment.—In regard to the treatment, it would be merely that for any chronic inflammation, or induration. I believe that if the tumor attains any very great size, nothing can be done; but I have diminished it by the administration of iodine externally and internally. I have successfully treated many cases in this way, but I have seen others in which treatment of this description failed. Of course, if there be pain on pressure, local bleeding, mercury, and the common remedies for inflammation, would be proper. Where the disease has arisen from malaria, it would certainly be well to give the sulphate of quinine; because I have seen improvement take place where the constitution has suffered from malaria, and I have also seen enlargement of the liver much diminished and give way with very little other trouble. If, therefore, there had been any exposure to malaria, I should give the remedies for ague; but iodine frequently, I know, has a consi-

derable effect in diminishing diseases of this description. Sometimes there is no pain whatever; and there, of course, you would not think of applying leeches or bleeding the patient. But if there be pain on pressure, local bleeding ought to be resorted to in proportion to the general affection.

Induration and softening of the Spleen.— Sometimes, without any enlargement, you will find the spleen exceedingly hard, cutting exactly like liver; and sometimes, on the other hand, it will become exceedingly soft. Very often, where you could discover no particular ailment referrible to the abdomen during life, you find the spleen soft. If it be not preternaturally hardened, you may, by working it up in your hand, bring it to the consistence of currant-jam; but in various diseases you find that the spleen, on cutting into it, is soft.

Accumulation of Blood in the Spleen.— The spleen, of course, suffers a great accumulation of blood when there is any obstruction to the organs of respiration. It is supposed by some that the size of the spleen may depend very much upon the mole in which patients die. If they die after long-continued dyspnoea you may find it large, although, during life, previously it was not so enlarged.

Tubercles of the Spleen.— Tubercles of various kinds are found in the spleen, and I met with a singular instance the other day of a large number of vessels in the spleen in a state of ossification.

Splenic Calculi, &c.— Calculi have been found in the spleen, and, as I have said, tubercles of all descriptions; but diseases of this organ are not very apparent unless the organ itself becomes enlarged. You know it is said that people can do as well without this organ as with it; and since the time of Galen, persons have amused themselves with cutting out the spleens of animals, and have said that they perceived no difference afterwards. It is said that the spleen, as well as the pancreas, has been absent by nature; but such things must be exceedingly rare.

so extraordinary as to the quantity of fluid secreted and removed by operation within a limited time, that I am induced to request your insertion of it. I have, indeed, seen a larger quantity removed by operation at one time than in either of the operations performed in this,— (for instance, Mr. Keate removed, at St. George's Hospital, 75 pints from a woman with ovarian dropsy, leaving some solid tumor still behind;)—and there are also cases on record of a larger quantity of fluid having been removed altogether, during the patient's lifetime, but I know of none in which the quantity was so large within a certain period, nor have I met with any person who has seen any case at all approaching to this.

I am, sir,

Your obedient servant,

CESAR HAWKINS.

Half-Moon Street,
June 10, 1833.

Mrs. D. æt. 34, observed a tumor in the abdomen for the first time about April 1830.

She attended as an out-patient of St. George's Hospital for some time, under the care of Dr. Seymour, without succeeding in getting rid of her disease, and as it at last increased, so as to give her great distress and difficulty of breathing, I was requested to remove the fluid, which I did for the first time in November 1830. The operation was repeated while she continued in the hospital, since which time I have performed the operation at her own home. During the whole of this time her health continued pretty good, except when the distention became very great, so that it was only for a few days before each operation that she suffered much pain and difficulty in respiration, requiring the use of opiates to procure any respite from her sufferings. The fluid which was evacuated was uniformly clear and transparent, looking more like the fluid of peritoneal dropsy than that of an ovarian tumor, except on account of its slightly mucilaginous appearance. It was almost always of a slight yellow colour, or nearly colourless, except on one occasion, when it had a brown colour, resembling the more common appearance of the fluid drawn from an ovarian tumor; but this appeared to have been owing to mixture with blood, as at the previous operation there was a stream of arterial blood from one of the vessels of the sac, which was readily controlled, however,

CASE ILLUSTRATIVE OF THE
QUANTITY OF FLUID SECRETED
IN OVARIAN DROPSY.

To the Editor of the Medical Gazette.

SIR,

THE following case of ovarian dropsy is

by gathering up the integuments and the sac between the fingers, and making pressure for a minute or two. The fluid was uniformly destitute of albumen, and seemed to consist almost entirely of water mixed with mucilage, or mucro-extractive matter, as it has been called by Dr. Marcet; it resembled, therefore, the contents of the aqueous encysted tumors of the liver and other organs, of which I ventured to give some account at the meetings of the Medico-Chirurgical Society, a short notice of which may be seen in the Medical Gazette, vol. xi. pp. 390, 748.

There never was any inflammation of the sac, nor any other inconvenience from the operations; but erysipelas of the abdomen coming on a few days after the last puncture, the sac appeared to participate in the inflammation of the parietes, to which it was adherent, and contained after her death, on the 20th of May last, about two gallons of fluid, such as is usually seen in inflamed ovarian sacs: it was now thick and very adhesive, and mixed with a good deal of lymph and purulent secretion, with increased vascularity of the sac.

The account of the operations performed is as follows:—

Operations.	Date.	Pints	Interval since the previous operation.
1st	November 1830	32	...
2d	February 1831	30	3 months.
3d	May . . . —	30	—
4th	Aug. 20 . —	40	—
5th	Oct. 18 . —	32	59 days.
6th	Dec. 8 . . —	48	51 —
7th	Jan. 18 . 1832	48	41 —
8th	Mar. 3 . . —	48	41 —
9th	Apr. 14 . —	50	42 —
10th	May 20 . . —	50	36 —
11th	June 26 . —	52	37 —
12th	July 30 . . —	50	34 —
13th	Sept. 3 . . —	56	35 —
14th	Oct. 10 . . —	56	37 —
15th	Nov. 19 . . —	56	40 —
16th	Dec. 22 . . —	57	33 —
17th	Jan. 24 . 1833	58	33 —
18th	Feb. 26 . . —	59	33 —
19th	Mar. 30 . . —	63	32 —
20th	Apr. 30 . . —	63	31 —
Total, 978 Pints.			

It will be seen from the preceding table, that the operation was required twenty times in *two years and a half*;

there being drawn off on the average about 44 pints of fluid; the smallest quantity at any one time having been 30 pints, and the largest 63 pints—the whole quantity being 978 pints. It will be observed also, that in *in one year* the operation was performed *eleven times*; the average quantity being above 56 pints, and the longest interval between any two operations having been 40 days; the whole of the fluid which was taken away amounting to the immense quantity of 620 pints in one year. During this time, therefore, there must have been secreted into the sac not much less than one pint and three quarters every day, although the quantity of liquid which she drank was often believed by her to be much less than this; and she secreted some urine also, though not much. Notwithstanding the immense quantity which was thus formed, she did not, till within the last few months, lose flesh much, nor was her general health much disturbed; neither did the immense size of the tumor cause any swelling of the lower limbs.

The fluid was all contained in one sac, so that the puncture was always made in the linea alba, nor was there any appearance of tumor left after the operations, till the last one or two, when I could feel something like solid tumor after the fluid was evacuated. On examination after death, however, a great number of smaller cells were found, containing different kinds of fluid, some of them having fluid like that generally evacuated, others containing purulent secretion, like that in the principal sac, and a few containing half solid gelatinous substance, like white of egg. The largest of these cells contained about a quart of fluid; the rest were much smaller, and they were all situated at the back and lower part of the chief sac, into which some of them projected. There was not in any of the cells any scrofulous matter, nor was any portion like that kind of ovarian tumor which resembles fungus hæmatodes in its appearance, many cases of which kind of tumor, which fell also under my observation, are published by Dr. Seymour in his work on the Ovaria.

There are two remarkable cases on record of ovarian dropsy, in which the whole quantity of fluid drawn off from the patients by operation was even greater than in the case which I have related, but the rapidity with which the fluid

was secreted was much less than in my case. In one of these, Mr. Martineau, of Norwich, says he removed in twenty-five years the enormous quantity of six thousand six hundred and thirty-one pints. In each year, therefore, on an average, there were two hundred and sixty-four pints of fluid, while in my case the average was for each year three hundred and ninety-five pints. Another well known case is related by Dr. Mead, in which the quantity of fluid drawn off was one thousand nine hundred and twenty pints in the course of five years and a half, which gives on an average three hundred and forty-nine pints for each year: this quantity is, therefore, nearer to, though still inferior to, what was secreted in the case of my patient. Dr. Mead's patient was tapped no less than sixty-seven times during five years and a half, or twelve times in each year, the average in my case being only eight times in the same period; but then, on the other hand, the average quantity of fluid drawn off in Dr. Mead's case was only about twenty-nine pints, while in my patient it amounted to about forty-nine pints.

ON THE
DISEASES OF MONTSERRAT,

AND THE

Fish Poison of the West Indies.

By DR. JOHN BADHAM.

[Concluded from page 242.]

IN resuming the short notices which my limited experience has enabled me to furnish respecting the diseases of Montserrat, I have next to mention, that it has not occurred to me to notice any cases of strictly cerebral disease. Insanity, melancholia or fatuity, are, with one exception of the former, entirely unknown to me among the negro population. As I am not studious of any nosological order, I may here mention, however, that I have met with cases of hydrocephalus in black children—that is, if I am entitled to form the conclusion from the death of the patient under the ordinary symptoms; and though I am aware that these symptoms are very misleading, especially in its earlier stages, yet I take it for granted, that a fatal termination of them, preceded by

blindness, insensibility, or strabismus, are sufficiently conclusive, though no examination should have taken place. Negro prejudices seldom oppose, in my opinion, any obstacle to examination after death, as is generally believed; but the reader will see that the heat of climate, and the great fatigue of the practitioner in his attendance on the living, will naturally abate some of his zeal for this instructive branch of his profession.

Cases of sudden death are not rare among the negroes. I have assisted at, or become acquainted with, the results of perhaps thirty inquests, and do not recollect more than one of these cases in which death was attributable to apoplexy; and that was the case of a female whom I found senseless at the commencement of labour. I delivered her in this comatose state by instruments; death, however, ensued; and on examination, the ordinary hæmorrhage on the brain was found. Some other cases of sudden death were from pulmonary hæmorrhage, from aneurism, from lightning, including two suicides, one a man, the other a woman. Adding to all these remarks, that I never witnessed a case of epilepsy in a black subject, it is impossible not to draw the conclusion, that, notwithstanding the laborious life and the exposure of the slave, his liability to cerebral or sensorial diseases is small. But this observation can by no means be extended to spasmodic complaints. I may have seen half a dozen cases of trismus nascentium, which were all fatal but one; and the cure in this instance was effected by large doses of *spt. terebinth.*, both by mouth and by injection. I have seen several cases of traumatic tetanus which were also, but with one exception, fatal. In this case the patient, a negro of Herculean strength, had incurred the disease in its severest form, by wounding the sole of the foot with a pine thorn; he recovered (after a prejudicial use of the cold affusion) by exceedingly large doses of muriated tincture of iron, of which he took about two ounces during the day and night, and wine *ad libitum*. I have also seen several cases of tetanus from cold; the result of these cases was generally favourable. Cases of spasmodic asthma are occasionally met with; and, contrary to what one would suppose, I have seen cases of humid asthma from bron-

chial congestion, but hooping-cough never, though ordinary coughs are sufficiently common. Dropsy is a very common complaint among the negroes, and ascites the most common form. It fell to my lot to tap one person for the thirteenth time; here an hypertrophy of the liver was present; in another, scirrhus uteri; but I am not inclined to believe that this form of dropsy, ascites, is, among the negroes generally, to be referred to organic causes. Of dropsy referrible to a cause analogous to inflammation, the West Indian practitioner has considerable experience. A man has danced the Banglee all night, and is exposed, while his body is sweating profusely, to a squall of wind and rain; he is apt, in such circumstances, to become suddenly anasarcaous from head to foot. Bleed him, then, to deliquium, and administer a large dose of cream of tartar, and at night give him a grain of elaterium, or a scruple of calomel, and the cure will frequently be as speedy as the disease (supposing always the subject to be young, and of unimpaired constitution.) Palsy and chorea I have not met with, nor have I seen true hysteria among the blacks. Urinary complaints of all kinds are scarce; calculus never exists. Of diabetes, in this land of sugar, I never saw one case. Rheumatism is abundant; colchicum, calomel, and opium, are the remedies. The subjects I have hitherto mentioned are all sufficiently familiar to European practitioners; but I will now say a few words on two or three that are out of the course of their experience.

The disease called the *rose* in the West Indies is not the same as the erysipelas, for which in Europe it is often used as synonymous. The lower extremities are the common seat of this complaint. The limb, or limbs, become swelled to an enormous size, and entirely lose their shape. The œdema is sometimes doughy; at others very hard, and quite void of colour. It is strictly a chronic swelling, and unfortunately in most instances a permanent one, utterly incurable by any medical treatment. In some cases, indeed, an inflammatory state of the skin does supervene upon the œdematised member, which then puts on a bright red and shining appearance, like oiled silk; this aggravated state may be relieved, but the *rose* (by which term the essential swelling only is distinguished) remains undiminished, except in a very

few instances where, being dissipated, the skin is left flaccid and inert. As to the pathology of this complaint, I take it to be a peculiar deposition or infiltration of fluid into the cellular texture, leading to a thickening or induration of that tissue. I should say that there is another form of the complaint more like the common erysipelas of Britain, and yielding to the same treatment; but the disease above described frequently begins and is established without any ascertainable inflammatory symptoms: to which I may add, in conclusion, that the disposition to contract it seems hereditary; it affects all ages, and both sexes, and is so frequent, that I may venture to say I have seen hundreds of cases of it. I have met with several cases of elephantiasis, which is perhaps not without some analogy to the complaint of which I have above attempted the description; and in one instance where it was confined to one leg, I saved the patient by amputation, and the disease did not return.

I shall now add some brief remarks on a subject which will have at least the merit of novelty to some of your readers, respecting the poisonous fish which frequent the coast, chiefly (and it is not a little remarkable) on one side of this small island; stating merely, not what I have read, but what I have witnessed; and, unfortunately, also experienced. There is the yellow-billed sprat, the effects of which are deadly. It is rather larger than the common sprat, which is *recherché*. Of this fish I have never witnessed the effects on the human constitution, but the detection of one, in a batch of sprats, is an affair which the curious in those matters will not always leave to the quick-sightedness of the cook: I conjecture that the mushroom of Agrippina, or a full dose of the doubtful hippomanes would be less speedy in its operation. The barracuda is a fish of large size, bearing some external resemblance to salmon. It is remarkable that this fish, every where coveted for its fine flavour, is perfectly harmless at Antigua, (at the distance of about thirty miles) while at Montserrat, if caught at one side of the island, *caveat emptor!* Of course I do not vouch for this exact locality, but it is the current opinion; and the negro fishermen will accelerate the bargain you are about by an assurance that the dainty he proposes to you was "caught north." As

this fish, however, is only poisonous by contingency, (one may be so, and a dozen others not) it is usual to test his sanity by giving the head to a dog. Some, indeed, keep a negro as a poison-taster on purpose. The fellow gets hardened, it makes him ill, but does not kill him. I hope my friends, the planters, will contradict this statement: it cannot possibly be true. Those who cannot afford to poison a dog, or a black, take their chance: if they hit upon the wrong fish, the symptoms that follow are unequivocal—sickness, violent tormina, (which arise from inflammation of the mucous membrane) and a prodigious collapse of the nervous power—a sort of cholera. I was once called to give my aid to seven sufferers under this affection in one day; and from partaking of one fish, they had violent singultus, but could not vomit freely; they had acnte gastralgia, (for I do not know whether to call it gastritis) and an intolerable pungent itching, (for want of a better word) a painful crethismus, as if the skin were pierced at a thousand points by needles over the whole body. Of these, my patients, four recovered, but three died. One expired on the third day, I think; one in about a week; and the other struggled on for nearly a fortnight. I remarked in all these cases a very peculiar sour exhalation from the whole body. One of the patients, who did well, had the worst symptoms by far; he was convulsed, in which state they commonly die. I, too, have had my dose of barraeuda, and suffered the most alarming symptoms—prostration of strength, cold perspiration, with a sense of internal burning. I was long ill, and in my case a discharge of blood from the bowels was not the least formidable of the consequences. I was, in short, many weeks in recovering, though I accelerated my convalescence by a sea voyage, by embarking for England. My dysentery lasted for a fortnight, and my constitution had plainly received a violent shock.

Fearful of intruding too long on a miscellany destined to carry more important intelligence than mine to every corner of the island, I will conclude with a case of *Obeah*. A negro woman was already in the pains of parturition, when she was suddenly bewitched or spell-bound, either by some ill-disposed neighbour, or the hallucination of her own brain. She saw the demon, or

some demon, squatting on her bed, and pointed out her enemy to me. As no directions in the printed books could help me or her, I thought it best to see what she saw, and making a sudden spring at it, by good luck I came off victorious, and amidst a thousand “thank you, Massas,” completed the humble office for which I was called—having the satisfaction of leaving my patient and her child “as well as could be expected.”

I have the honour to remain, Sir,
JOHN BADHAM, M.D.

Workshop, Notts, 8th May.

OBSERVATIONS
ON THE
COLCHICUM AUTUMNALE.

By R. BATTLEY, Chemist.*

THE *corpus* of *colchicum*, commonly called the root or bulb, attains its full size about June or July, from which time to the middle of August both its sensible and medicinal properties exist in the highest state of perfection.

At the beginning of June it will be found to have produced from its base a germ or offset. And if a vertical section be made at this time through the centre of the bulb, the part nearest to the offset will be found somewhat transparent, and traversed by white streaks, which appear to be the principal lines of absorption. This transparency indicates the commencement of a chemical change by which the bulb is adapted for the nourishment of the offspring. The greater part of the bulb, however, remains unchanged until about the middle of August, when it becomes unfit for medicinal purposes.

This internal change is not indicated by any corresponding alteration in the external character of the bulb. During the ensuing autumn and winter, and even up to the beginning or middle of April, it appears equally large, firm, and plump, as in the preceding June or July; but its medicinal, and in great measure its peculiar sensible properties, have ceased to exist. From this time

* Part of the following observations were published in 1820, in the fourth volume of the Medical Repository, page 29. They are now reprinted with some alterations, in order to complete the subject.

also its substance begins to decay, and by the end of May it has entirely disappeared.

The germ or offset which is developed within the outer coat or tunie of the parent bulb, produces in September two or more flowers, unaccompanied by leaves. At this time it forms a small protuberance about the size of a bean, and is lodged in a depression of the old bulb, which embraces it half round.

During the remainder of the autumn, and the greater part of the winter, the offset is stationary; but on the return of spring, or even at the beginning of February, it recommences growing, producing first its leaves, and after some weeks its seed-vessel, which, having remained during the winter below the surface in the summit of the bulb, is now elevated on a peduncle, and ripens about the time of hay-harvest.

In the meanwhile its bulb has become firm, plump, and heavy, and has formed a new germ on the side opposite to that by which it was itself attached to the bulb of the preceding year.

A second offset is also formed about the same time above the first, and on the opposite side; but it is much smaller, and rarely flowers.

Anatomy of the Bulb.—A bulb was dug up on the 1st of February, the leaves projecting half an inch above the ground. It was irregularly fig-shaped, having the offset on one side. With the exception of the root and the upper part of the leaves of the offset, the whole was enclosed in a smooth, dry, thin, brown tunie, arising from the base of the bulb. On removing this tunie, the bulb appeared of a cream colour, having a longitudinal groove or depression on one side, which was occupied by the cylindrical offset. The offset was enclosed in a proper tunie, arising from its base, membranous above but fleshy below. Inferiorly it terminated in an irregular swollen base, which projected half an inch beyond the pared bulb, and gave rise to a bundle of long vigorous fibres, and superiorly in four leaves, above two inches in length, which enveloped each other, and were invested by the proper tunie. The two outer leaves arose from the lowest part of the offset, and enclosed its bulb or swollen base, which was half an inch in its transverse diameter. The bulb terminated in a short neck, about two lines in length, which supported the two inner leaves. Within these latter were

two cylindrical three-celled capsules, about a quarter of an inch in length, filled with minute rough seeds.

On the opposite side of the old bulb, and towards its upper part, was the decayed body of a second offset, with a bundle of fibrous roots attached to it.

Time and Mode of Preserving.—The bulb being removed from the ground about July, will be found full-grown, plump, and heavy. If it is kept in this state, the offset, which is already formed, will continue to grow, and the properties of the bulb will be consequently impaired. In order to prevent this occurrence, the outer coat is removed, and the bulb cut into transverse slices, about two lines in thickness, which are dried by exposing them for about two hours to a temperature of 150 degrees Fahrenheit. In this state colchicum will keep for any length of time. It gives out its properties to wine, proof spirit, and vinegar, but apparently not to alcohol. It loses about sixty-seven per cent. of its weight in drying.

The fresh cut surfaces are covered with a milky juice, which, if removed, is instantly renewed. This milky juice is slightly acrid, but does not blister the skin. It gives to the tongue a peculiar earthy taste, and a sensation of coldness, which continues about half an hour.

The dried slices are cream-coloured, firm, and friable; and though previously circular, are now concave on the side which at a later period would embrace the offset. To the taste they are slightly bitter, and if retained in the mouth diffuse a general warmth over the fauces.

During the autumn and winter, the characteristic cold and earthy taste of colchicum becomes continually less and less distinct, and in the spring it is entirely lost; and slices of the root dried at this time, instead of remaining firm and friable, shrivel up like leather exposed to fire. Slices dried in June, when the offset is still very small, become concave on the side which forms it, lose seventy-five per cent. of their weight, and become shrivelled and porous.

Preparations of Colchicum.—On the 1st of August, 1823, the following operations were commenced on forty-two pounds of colchicum roots:—

The roots were bruised, and yielded, under heavy pressure, twenty pints of a drab-coloured creamy juice. This juice was slightly acrid and bitterish, and

impressed the whole mouth with its cold earthy taste. It had also a peculiar earthy and slightly pungent odour. After standing twenty minutes in a wedgwood dish, the juice had deposited a copious white sediment. The supernatant liquor having been decanted, the sediment was firm, unyielding, dry under pressure, and minutely granular, and was with difficulty removed from the bottom of the vessel. After repeated washings with cold water, it was dried, and weighed two pounds twelve ounces. It consisted almost entirely of starch, and tasted slightly of colchicum.

The liquor was placed in a wedgwood dish over the steam of water at a temperature not exceeding 150 degrees Fahrenheit. When reduced to the consistence of an extract, it weighed one pound nine ounces. It was adhesive, of a dirty-drab colour, and retained its peculiar odour and bitter earthy taste.

This preparation, which has received the name of *extractum colchici recentis*, appears to be the most effective and uniform of all the preparations of colchicum.

The liquor *colchici recentis* is prepared from this extract by the addition of eight parts of distilled water. To every pint of the liquor, previously filtered, is slowly added one ounce of rectified spirit first diluted with a little distilled water, which occasions a slow precipitation of a brown matter, the separation of which enables the medicine to keep for any length of time without decomposition.

The liquor may, however, be prepared more directly by stopping the evaporation of the expressed juice, previously deprived of its starch, at the point when it has acquired the consistence of a thin syrup, and the diluted spirit may then be added in the above proportion.

If a much larger proportion of spirit is added, it precipitates abundance of gummy matter; and after a few days, a white scaly substance, which on examination appears to be alumina. The separation of this latter substance renders the medicine comparatively inert, and must therefore be carefully avoided.

Similar operations will be commenced at the Ophthalmic laboratory on the 1st of July, on four kinds of sarsaparilla, viz. Lima, Jamaica, Lisbon, and Vera Cruz, to which the attention of the profession is particularly directed.

Ophthalmic Laboratory, Moorfields,
June 28, 1833.

BITE OF THE VIPER.

To the Editor of the Medical Gazette.

SIR,

If you think the two following cases contain any thing new, and deem them worthy of insertion in the *Medical Gazette*, they are much at your service.

We are, sir,

Your obedient servants,

TAYNTON & WILLIAMS.

Bromley, Kent, June 21, 1833.

CASE I.—*Recovery from the Bite of a Viper.*

Michael Slow, aged 21, was bitten by a viper, in the thumb of the right hand, a little before five o'clock on Sunday afternoon, June 2d. His hand began to swell in ten minutes after the receipt of the injury. Soon after, he vomited and was purged. We saw him at half-past five. The skin was of a livid hue; the tongue was so swollen that he could not speak without great difficulty; the pulse was hardly to be felt, and the prostration of strength universal. The hand and arm were much swollen. We gave him two *full* doses of the *Sp. Ammon. Succin.* (30 drops in each dose) in ten minutes, and with the second dose 30 drops of *Tr. Opii*. The medicine appeared to rouse him from the state of stupor in which he had hitherto remained. He afterwards took frequently some *Sp. Ammon. Aromat.* and the bitten part was kept constantly wetted with it. The bowels were moved twice in a quarter of an hour, but he did not vomit any more. The arm was constantly fomented during the night, and the volatile alkali given frequently.

June 3d.—He had passed a very restless night. The hand and arm very much swollen, very hard and much discoloured.

4th.—Rather better. The tongue less swollen; vesications round the wrist, and above and below the elbow. The internal part of the arm, from the elbow to the axilla, of a deep livid colour.

5th.—Better. The arm much the same. Bowels constipated; took three purgatives before any effect was produced.

10th.—Nearly well. The swelling of the arm almost subsided, and the discolouration entirely gone.

We had a similar case under our care

some years ago, in which the same plan of treatment was pursued with equal success.

CASE II.—*Great Enlargement of the Tongue.*

William Durling, aged 30, was brought to Bromley, from a village four miles distant, in the evening of June 18th. His appearance was truly distressing. His face and ears were of a dark purple colour; he breathed with difficulty; he could not speak, and had not been able to swallow any thing for twenty-four hours. All these symptoms were occasioned by an enlarged state of the tongue. He first perceived the swelling on Sunday evening, the 16th. It had continued to increase from that time. His wife attributed it to his having remained for some hours in wet clothes. Upon examination, the tongue seemed prodigiously swollen and hard, and very painful if pressed. The skin was hot, and the pulse quick. We scarified the sides and under part of the tongue very freely; about five ounces of blood were quickly obtained, from which he experienced much temporary relief. He was desired to hold warm fluids in the mouth constantly, and to apply a large linseed poultice all round the throat.

Early the following morning a message was brought that he had passed a miserable night, and it was supposed that he could not survive many hours. On our arrival we found him in great distress. He had not been able to swallow one drop of any liquid, and felt as if he should be suffocated every moment. We again made several deep incisions in the sides and tip of the tongue. The blood flowed very freely, to the amount of eight ounces. A large blister was applied from ear to ear. Two drops of croton oil were got down with great difficulty. At 7 p.m. he was better; was able to speak so as to be understood, and had swallowed some milk. He had vomited, and the bowels had been very freely opened.

On the 20th he was better in every respect. The swelling in the tongue was considerably diminished, he was able to swallow broth and milk, and had slept for several hours.

On the 21st he was almost well.

P.S.—I feel anxious to lay this case before my medical brethren, as, in the

course of forty years' practice, I have never met with any thing like it; and I have not been able to find any medical writer who treats of such an affection satisfactorily.

R. T. TAYNTON.

MODE OF APPLYING FRICTION.

To the Editor of the Medical Gazette.

May 22, 1833.

SIR,

I HAVE for some time recommended an instrument of which the following is a description; and as I am now convinced of its utility in cases where friction (in any of its modifications, as shampooing, the douche, &c.) is an appropriate remedy, I think it of sufficient importance to give it publicity. From time to time, in the course of many years extensive opportunities in England and on the continent, I have, I believe, witnessed the employment of all the means that have been recommended for the purpose of assisting and reanimating torpid circulation, from the *Remedium arenarum et arundinum*, to Adm. Henry's pomeling hammer, Dr. Gower's pulsator, and the still more recent plans of Dr. Balfour; but having found that these methods were either inefficient, or attended with inconvenience, I was led to the construction of a percussor, which I hope will be found as valuable an auxiliary by the profession generally, as I have uniformly found it to be.

Description.—Two balls of India rubber (varying in size according to the part to be operated upon) are affixed to the extremities of a circular whalebone rod, fifteen inches long. One of these balls admits the egress and ingress of the air, and depends for its form upon its own elasticity, assisted by a small quantity of curled hair; the other is hermetically sealed, and its figure is preserved by the air contained. Upon the circular rod is a moveable handle, which regulates the length of the lever, and consequently the spring and stroke given by the instrument. By a slight movement of the hand a rotatory motion is given to one of the balls, and it may thus be applied so as to produce the effect of the gentlest friction, or be increased to that of the most powerful shampooing.

If the compressible ball is placed for

a few minutes before the fire, it of course becomes more pliable and yielding; and as that hermetically sealed is always in a state of tension, the quality of the ietus may be modified at discretion. Leaving to the discrimination of the profession the cases in which this instrument may be employed with advantage,

I have the honour to be, sir,
Your obedient humble servant,
J. P. HEATH, M.D.

P.S.—It is hardly necessary to observe, that this simple instrument may be applied by an ordinary nurse, or in many cases by the patients themselves.

THE APOTHECARIES MUST EXAMINE M.D.'S.

To the Editor of the Medical Gazette.

SIR,

It is the recorded opinion of yourself, and it is an opinion which many persons are glad to reiterate, that the Court of Examiners of the Apothecaries' Society have acted *injudiciously* by subjecting to an examination those candidates for a license to practise as apothecaries who have already obtained from the universities of Scotland diplomas constituting them doctors of physic.

But I apprehend, as the law *now stands*, the solemn oath administered to the Court of Examiners leaves them not at liberty to consider what is more or less *injudicious*: they must abide by the oath they have taken. The law will probably be altered: the Court of Examiners will be deprived of the power they now possess of examining Scotch graduates, and the Court will feel that they are exonerated from a very painful task, which hitherto a sense of duty only has stimulated them to fulfil.

Whether it will be judicious to deprive the Court of Examiners of this power, time is to shew. If in Scotland a more exact examination of candidates is adopted, it may answer very well, otherwise the public will gain nothing by such an alteration of the law.

For if the result of the *injudicious* examination of Scotch graduates be inquired into, it will be found that *one-third* of those who have applied for certificates of qualification have been re-

jected as incompetent to practise as apothecaries. In the short space of twelve months, of twenty-four Scotch graduates who appeared before them, the Court were compelled to reject eight: this may have been *injudicious*, but it was *conscientious*: it may have been *impolitic*, but it was *just*; it may have raised them many enemies, but it was in accordance with their solemn oaths.

It may be asked, how is it possible that persons who have gone through the examination of the Scottish Colleges, an examination so close and scrutinizing that it has been held up as a model to all others; how is it possible that persons who, after such an examination, have been dignified with a diploma, who have been privileged to affix M. D. after their signatures; how is it possible that graduate doctors of physic should think of being examined as apothecaries, and being so examined, should be rejected as incompetent?

To this question it is difficult to return an answer, but it may be conceived possible that sometimes at the Scottish colleges, some students have obtained their diplomas nobody knows how. On some occasions the examinations have not been quite so strict as at Apothecaries' Hall; for if they had been as strict, such graduates as have failed at the Hall would not have passed at the Universities. Fortunately, for the honour of the Scotch colleges, these less qualified graduates have been so conscious of their inferiority to the many eminent and enlightened physicians who have proceeded from Edinburgh and Glasgow, that they have felt it right to quit the higher grade of physicians, and to take upon them the more humble station of apothecaries or general practitioners; they have been willing to lay aside the baton of Æsculapius, glittering with the golden vesture of the serpent, and to substitute the brazen mortar, clanging with the strokes of the pestle; but surely when these graduates thus acknowledge themselves unfit to be physicians, it is only reasonable that they should prove themselves competent to become apothecaries. If it be *injudicious* or *impolitic* to examine them, at least circumstances have proved that it was right, for, as before stated, a large proportion of such graduates have failed to prove their competency.

It is of course impossible that much can be known of the circumstances

which led the Court of Examiners to reject so many of them, but the rumours and whispers which the rejected candidates have spread abroad of insufficient and unsatisfactory grounds for such rejections, have been met by other rumours and whispers, which completely justify the Court for the course they adopted. And here let it be noted, that in no one instance did the rejection proceed from the hastily-formed opinion of one or two or three Examiners; no candidate was rejected, except after an examination personally witnessed by a majority of the Court, and upon the report of the examination being made to the whole Court, every individual member concurred in the propriety of the rejection.

If still there be any doubt of the justice of the rejection, why do the rejected candidates not call for and publish the minutes recording the causes of their rejection?

CONSERVATOR.

June 25, 1833.

[The explanation contained in the preceding letter, and which we have ascertained to be authentic, is perfectly satisfactory as to the necessity the Council is under of examining medical graduates.—ED. GAZ.]

APPRENTICESHIP CLAUSE IN THE APOTHECARIES' ACT.

To the Editor of the Medical Gazette.

SIR,

YOUR correspondent Σ , p. 429, quotes a maxim, "audi alteram partem," which, however trite, will always retain its high value; and as he is so desirous of hearing both sides of the question, I will take the liberty of giving him some information which he appears not to have obtained. He asks whether the Court of Assistants of the Apothecaries' Society do or do not act *honourably* in refusing an examination to a candidate who is unable to shew an indenture of apprenticeship for five years to an apothecary? And in another part of his paper he *insinuates*, that "these impartial examiners" were "guilty of getting up a job" "in petitioning the legislature for the Act of 1815."

In reply to this insinuation against the Court of Examiners, "these impartial examiners," it needs only to be

mentioned, that till the Act of 1815 passed into a law, there were no examiners appointed, and therefore they could have no share in the guilt "of getting up the job." But if there were no examiners, there was the Society of Apothecaries, and Σ may probably plead, that he did not mean the Court of Examiners, but the Company itself. Now for the fact: When the General Association of Medical Practitioners, to which Σ alludes, had obtained leave to carry a bill through Parliament, for the improvement of the profession, the preparation of the bill was entrusted to the Master, Wardens, and Court of Assistants of the Apothecaries' Society, who accordingly did prepare a bill, which had the sanction of the College of Physicians, and of the acting Committee of the "General Association." Now mark! The bill, thus prepared, did *not* contain the clause insisting on an apprenticeship as a qualification for examination; but such a clause being thought by some members of the legislature essentially important, was introduced into the bill during its progress through the Houses of Parliament; and the agents for the Company of Apothecaries were given to understand, that without such a clause the bill would not be allowed to pass. Under these circumstances the Society yielded to what they could not prevent; and the same Act of Parliament which required and authorized the Master, Wardens, and Court of Assistants to elect *annually* twelve members to form a Court of Examiners, strictly prohibited and forbade that Court from admitting to an examination any person who has not served an apprenticeship to an apothecary for five years.

I now beg to ask Σ , whether it would be *honourable* in the Court of Examiners to do that, which they are expressly forbidden to do by Act of Parliament?

TAU.

June 30, 1833.

Σ likewise stigmatizes the Court of Examiners for requiring certificates from the candidates of *good moral conduct*; but how they can judge of the good moral character of the young men, unless by certificates, he does not inform us. It seems as if he thought, whether of good or of bad moral conduct, that all candidates, tag, rag, and bobtail, ought to be admitted to examination by the Court of Examiners.

ON THE
STUDY OF POLITE LITERATURE,

AS CONNECTED

With the Practice of Medicine.

—
To the Editor of the Medical Gazette.

Quod non imber elax, non aquilo impotens
Possit diruere, aut innumerabilis
Annorum series, et fuga temporum.
HOR. L. iii. O. xxx.

SIR,

EVERY man may be the author of his own intelligence, which is the endowment, not of any natural or hereditary right, but of scholastic or spontaneous tuition. Prominence of mind is consequential on self-instruction.

Now the materials of mind are almost coeval with the world; and they have been protected by the care of successive generations, so as to have survived the demolitions of nations and the occasional falls of literature, and still to remain as fresh and lively as they were on their first production. The works of the great masters of letters have been sanctified by time, and the ignorant revere what they cannot understand. These materials, original, sound, and strong, have, by their own intrinsic value, acquired for themselves the same jealous protection which, within the strength of battlements, is bestowed upon the regalia of princes. These are the gems and jewels of the learned world; the studs and bosses of the intellectual casket. Their lustre displays the excellence of mind, when rightly appointed and rightly set at work; their perpetual value assures the ascendancy of mind over brutal strength, when exercised upon the same subjects—the men and matter of this nether world. Cyrus lives by the pen of Xenophon, and the poet Dante has obtained a celebrity more lasting than the names of the political leaders with whom he was unhappily involved. Great deeds are dead without letters, and letters are dead without the exercise and discipline of the spirit proper to their direction; for deeds are the subjects of letters, and letters the servants of mind. Who, then, shall gainsay the efficacy of learning? Who shall affect to despise the study of polite literature? Unadorned with letters, the physician,

at least, is weak and deficient; an offence to others, and a burden to himself. The development of his own thoughts is beyond his masterdom, and scientific research, though it be necessary for the exact demonstration of truth, yet fails altogether in inspiring greatness of sentiment, greatness of manner, and greatness of execution*. A minute attention to trifling affairs diminishes the mind. The mere anatomist may lie concealed beneath the tissue of his minutest dissections; the mere botanist may become invisible on his cryptogamic specks of vegetation; and the mere chemist may be atomized with his own elementary particles of matter.

At this day, when science is dominant, I dare assert the superiority of letters; and would exhort some students to quit the recesses of dry analysis for meads of imagery and graceful flights of fancy.

Largior hic campos æther, et lumine vestit
Purpureo—

Manifold, indeed, is the utility of science, but its immortality can be sealed only by the pen, within the closet, and before the cloistered lamp†.

The gentleman and the man of letters will be always associated in person or in intercourse, as from thence deriving the principles of true taste and soundness of judgment. The experience of ages has already proved the utility of letters practically, in the highest stations; whether in the character of a Burleigh, a Bacon, a Cicero, a Franklin, or a Mead: and I am tempted to affirm that delicacy of sentiment is not an empty qualification, and that substantial profit is the fruit of polite studies, and a moral refinement of the intellect. The great masters of antiquity, and those later writers who have been guided and instructed by them, are the standards by which the studious labourer may raise, according to their primitive models, fresh combinations of

* The classic reader will readily recognize the greatness of manner here alluded to; and so will the classic painter.

† Polite literature, *per se*, is not knowledge—it is the *light* of knowledge; “a light that shineth in a dark place.” Knowledge may be claimed by science, but letters give life to science; therefore science depends upon letters: *sine literis est mors*. Letters are the life of mind, *mentis agitatio*; science the subject of mind (understanding), *species in animo*. — See *Harris's Hermes*, B. iii. C. iv.

thought, and new erections of knowledge, by which he may amplify the powers of language, and multiply the evolutions of sense. By them he is taught to feel as well as to think; to love and to illustrate, without abusing, dignity of rank and plenitude of power; but, above all, to beget himself a name perhaps co-existent with time, which is better than the merchandize of silver and gold, *regalique situ pyramidum altius*.

But learning is nullified by vice, and the intellect is already enslaved as soon as the moral will has submitted to the subjugations of passion. Who *will* speak the truth, when he is not true to himself? Who *will* think rightly, when he is daily doing what is wrong? Eru-dition, to be bold and potent, must be based upon virtue; and virtue, to be current in the world, must be exercised with modesty, benevolence, and sense: now these are the gifts of wisdom.

And this conclusion brings us back to the point from which we started, namely, the self-instruction of the mind, and its cultivation according to the best materials, which have been shewn to be both universal and good, the appropriate ornaments of the accomplished physician, or at least of the accomplished gentleman; for the ascendant of the physician does lie, not only in medical skill (which is a little office confined within the narrow pale of mortality), but also in politeness of intellect, and in a certain greatness and sagacity of perception, by which he discerns the moral as well as the physical nature of man. He no longer treats man as a statue carved according to the proportions of life, but man as a living sufferer, his fellow pilgrim in the world. By sagacity and politeness he ascends in the scale of intellect, and studies, not merely to merit from colleges the degrees of learning, but rightly to claim from mankind the aristocracy of talent. Thus fortified, ennobled, and exalted, he passes from the mere tactician to the moralist; he widely surveys the virtues or the vices, and consolidates them with the afflictions of men; he stamps on the fugitive duties of the day the lasting impress of divinity.

MEDICULUS.

May 24, 1833.

QUESTIONS FOR DR. PHILIP

ON THE
NATURE OF THE RESPIRATORY
MOVEMENTS.

BY PHILALETHERS.

DR. PHILIP states, (Vital Functions, Ed. iii. p. 191) in explanation of the movements of respiration, that, "by a certain *sensation*, a *wish* is excited to expand the chest;" and (p. 268) that "the lungs being supplied with nerves from the eighth pair, the *sensorial* powers, as far as regards them, (the lungs) cease when that part of the brain from which these nerves originate" "is destroyed."

Will Dr. Philip inform your readers, 1, why the respiration continues after the cerebrum and cerebellum are removed? And, 2, why the respiratory movements continue after the eighth pair of nerves is divided?—facts established by the experiments of Legallois, M. Flourens, and many others.

If respiration consist in voluntary movements, how does it continue after the seat of volition, and of all sensorial power, (the cerebrum) is removed, and after the channel to it (the eighth pair of nerves) is intercepted?

These questions cannot be considered as idle, if we call to mind that our two first physiologists, viz. Dr. Philip and Sir Charles Bell, are at variance in their opinions in regard to the voluntary or involuntary nature of respiration. *Succinct* and satisfactory answers to them would confer a great obligation upon the young student of physiology.

ILLUSIONS IN MANIACS.

M. ESQUIROL has deposited a memoir relative to the distinction in maniacs considered in a medico-legal point of view, and has read another paper entitled "Illusions in Maniacs." The design of the author is to distinguish clearly, in this new work, hallucinations from illusions. In the former, every thing, according to him, goes on in the brain: the visionaries are persons who rave quite awake, and whose cerebral activity is so energetic, that it invests with substance and reality the images which are produced by the memory without the intervention of the senses.

In illusions, on the contrary, the patients are deceived with respect to the nature and cause of their sensations. Illusions are not all rare in the state of health, but reason soon destroys them; whilst in maniacs the case is not so. Two conditions, in fact, are necessary for the perception of a sensation: integrity of the organ which receives the impression, and integrity of the instrument which reacts on the impression. If the sensibility and activity of the organs are disturbed, the impressions made by external objects must be modified; and if at the same time the brain is diseased, it cannot rectify the error of the senses: hence arise illusions. The very volatile attention of maniacs cannot rest long on external objects, and then the perception is incomplete: the patients perceive but badly the qualities and relations of the objects which make impressions on them: in monomania, on the contrary, the attention is too much concentrated, and cannot carry itself successively over the objects which are external and foreign from the prepossessions and conceits which predominate over the patient's thoughts. In a word, the mind and the passions concur with the senses in producing the illusions of maniacs: but it is from the senses that the process commences. Hypochondriacs have illusions arising from internal organs; they are deceived with respect to the severity of their suffering, but they are not actually bereft of reason, (*dérailonnement*), unless the case be complicated with *lypomania* or *melancholy*. M. Esquirol has examined the body of a woman at the *Salpêtrière*, who for a long time fancied she carried an animal in her stomach: she had cancer of this organ. An aged woman, who was very devout, and who laboured under monomania, imagined that she carried in her abdomen all the personages of the Old and New Testament; when her pains became very severe, she sometimes figured to herself that Jesus Christ was being crucified in her abdomen, and she said that she distinctly heard the blows of the hammer; when she was opened after death, they discovered the existence of chronic peritonitis, which caused extensive adhesions to all the intestines, so that they formed one mass. The same alteration existed, though less marked, in a demonomaniac who was extremely emaciated, who fancied that she carried in her abdomen

several devils, who were tearing her and inciting her to self-destruction. Her skin was as insensible as if it had been tanned, and M. Esquirol several times stuck pins into it without causing any pain. This woman stated that the devil had taken away her skin from her, and that he replaced it by his own. Irritation and pains in the organs of generation are oftentimes the cause of illusions in maniacs, particularly in women. The painful constrictions of the throat in hysterical monomaniacs, are often attributed by them to the effects of some jealous person who wishes to strangle them. The wandering pains which maniacs sometimes feel in their limbs also give rise to illusions. A medical student, in an attack of mania caused by the presence of worms in the intestinal canal, felt acute pains all over the body, and attributed them to darts with which he fancied himself constantly pierced. The illusion went off after the expulsion of the worms. The author next passes in review the cases where the illusion arises from the external senses. The derangement of the digestive functions, and the perversion of taste almost invariably observed at the onset of mental diseases, often make the patients, who find fault with their food, fancy that they have been poisoned: a circumstance which contributes to inspire them with an aversion for those who have charge of them. This illusion disappears when the digestive functions are restored to their natural state. It is very important to distinguish this refusal of food from that which results from a fixed determination, as, for instance, from a vow, &c. The first has nothing alarming in it; the second, on the contrary, is very difficult to overcome. The dryness of their mouth causes many maniacs to think that earth has been mixed up with their food, or that spoiled meat has been given them, &c. &c. After a very interesting examination of the illusions which arise from the alterations of the other senses, the author closes his memoir with the following conclusions. 1st. Illusions are the result of the actions of the sentient extremities, and of the reaction of the nervous centre. 2nd. Illusions are caused as frequently by the anomalous excitement of the internal organs as by that of the external senses. 3rd. Illusions set reason astray with respect to the nature and cause of

the impressions actually received, and excite the individual to acts more or less irrational. 4th. Sex, education, profession, habit, by modifying cerebral action, modify the character of illusions. 5th. Illusions assume the character of the ideas as well as of the passions which predominate in the persons affected. 6th. Illusions cannot be confounded with hallucinations, since in the latter the brain alone is excited. 7th. Finally, reason dissipates the illusions of the man who is sound in mind, whilst it is unable to destroy the illusions of maniacs.—*Archives de Med. Oct. 1832.*

DISCHARGE OF WORMS FROM VARIOUS PARTS OF THE BODY*.

JOHN ALEXANDER, aged 10 years, was for nearly a year in a delicate state of health; although his appetite continued pretty good, he had much wasting of flesh and general debility. About eight months since a tumor arose over the epigastrium, which after being poulticed for some days, burst and discharged, with about two ounces of pus, a white worm half an inch long. In a few days the abscess healed. Eight or ten days afterwards a second tumor arose, about three inches distant from the first, on the right side of the chest, which after some days also burst and gave exit to another worm. It is needless to particularize the different instances; suffice it to say, from the time of the first worm being discharged until I first saw him, which was an interval of two months, five worms had made their appearance. They were all similar to the first, and lived for a few hours after their discharge. When I saw him the integuments of the right cheek and eye were excessively swollen, and in the course of a few days another worm was discharged from the upper eye-lid. I recommended different medicines for the space of six weeks, but the formation of abscesses on different parts of the trunk and extremities proceeded, and altogether about twenty worms were discharged, principally from the right side. At length two grains of calomel were given every night until the gums be-

came affected, and convalescence shortly afterwards took place; I shall not pretend to say whether from mercurial influence, or from the produce of the original mias having been exhausted. The boy has been now for nearly three months quite well, his health and strength being completely re-established. The worms appeared to be ascarides. None were, however, at any time observed to be discharged from the intestines, nor were the bowels irregularly affected.

I cannot account for their formation: whether the first deposition of eggs had been made by some means under the external skin, or whether a worm had perforated the intestine, and at length made its way to the surface. I incline to the latter opinion, from the boy's previous ill health. I could in a few instances trace a reddish line from one abscess to the other; this was, however, after the new abscess appeared. The patient himself felt no uneasiness in the part, nor had he any idea where the next abscess would form until it appeared externally*.

PRESERVATION OF LEECHES BY FEEDING THEM WITH SUGAR.

THE attention of the Academy of Medicine has been lately called to this subject by a chemist. A commission was appointed to investigate particulars, and they have given in their report, which, however, is not favourable to the proposal.

The chemist was of opinion, that the blood which we so frequently find in the water in which the leeches are kept is not disgorged, but flows from the wounds which the animals inflict on each other when huddled together; the commission doubt the accuracy of this. A great error has very generally been committed, in supposing that one of the causes of the loss of so many leeches is the putrefaction of the "mucosities which exude from their bodies;" now these so called mucosities, are in fact the epidermes, which are regularly thrown off at intervals, in the same manner as the scarf-skin of a snake. The impressions of the rings of the leech are quite obvious on this mucosity; it is detached first to-

* Extract of a letter from Mr. C. Nelson, of Killala.

* From the Medico-Chirurgical Review.

wards the head, and the animal escapes from it as from a sheath, which still adheres for a short time to the tail, so that we often see the leeches swimming about with this membranous appendage.—*Bullet. Gen., and Med. Chir. Review.*

CICERO.

IRISH RECIPROCITY.

WHEN we spoke lately of the ill grace with which the Scotch came into England to demand the abolition of what they have been pleased to call a monopoly, and to seek the possession of privileges here which by law they cannot enjoy at home, they replied to us—that though these restrictions do exist in the letter, they have been long abolished in the spirit; and that they have never been acted upon “within the memory of man.” The presence of the beam they admit, but they say it does not obstruct their vision; and we suppose it is as a proof of this that they shew themselves highly offended with their neighbour’s note. There is nothing in the excuse bearing even the semblance of plausibility, except the consciousness which it betrays of the existence of something to be amended: and where a wish to remove what is narrow and illiberal is expressed, we can make large allowances. This, however, is not the case with a party of whose proceedings we mean now to take some notice, and with whose unblushing coolness we have been perfectly astounded. A deputation comes over here, from the Irish College of Surgeons, to seek a “reciprocity.” Let us state a few facts relative to the

conduct of these worthies in their own country, and it will presently be seen what sort of reciprocity they merit.

We have more than once called attention to the cunning clause inserted into the Irish Grand Jury Bill by the good people of the College of Surgeons in Ireland—bearing that the Grand Jury should pay no surgeon of a county infirmary who could not produce the diploma of *their* College; thus virtually excluding all other surgeons from situations of any worth in the Irish hospitals, to the grievous injury of a large and respectable body of practitioners in Ireland, holding the diploma of the London and other Colleges. Well, the outcry against this proceeding they found was becoming too strong for them, and there was evidently no chance of carrying the clause in the Bill, notwithstanding deputation upon deputation, stirring heaven and earth, to secure the desired object. Something else must be done. Another bill is prepared, before even the Grand Jury Bill is disposed of; and this new and most impudent piece of legislative chicane not only embodies the clause just spoken of, but, all decency aside, sets forth its obnoxious features in an aggravated form. In the second clause of this, which is denominated the Irish Infirmarys’ Bill, the names of thirty-one counties are mentioned, in which public infirmaries or hospitals are to be erected and established; and the sixth clause proposes, that “no person shall be capable of being elected a surgeon of any of the said respective County Infirmarys, or Hospitals, who shall not previously have obtained letters testimonial of his qualification, under the seal of the Royal College of Surgeons in *Ireland*, and that no other qualification or examination shall be necessary to make any person capable of being elected surgeon of any such Infirmary, or Hospital; and that no person shall

be appointed physician to any such County Infirmary, or Hospital, who shall not be examined and certified to be duly qualified under the seal of the King's and Queen's College of Physicians in *Ireland*." Yet the authors of this Bill are seekers of reciprocity in England.

But further: the Irish College, which seeks for its diplomatists the privilege of coming to settle in England on the same terms as the London College, not only are themselves unqualified to act in the capacity of apothecaries in Ireland, but, by a stupid conceit, bind their diplomatists not to exercise, as long as they would belong to the College, the art and mystery of the apothecary. Yet these are the seekers of reciprocity in England.

Again: the new Infirmarys aforesaid are to be furnished with apothecaries in addition to surgeons. Let us see what the reciprocity seekers have determined on in this case. Clause 16 ordains that the Governors of the said Infirmarys shall not pay the appointed salary to any apothecary who shall not have "served an apprenticeship to the art and mystery of an apothecary, and been duly examined and certified under the seal of the Governor and Company of the Apothecaries' Hall in *Ireland*." So that if an English general practitioner, or Licentiate of the Society of Apothecaries in London, were to seek the humble situation of apothecary in an Irish County Infirmary, he is virtually excluded by this Act, or proposed Act, of Parliament. Yet the exclusionists presume to come over here and demand a *reciprocity*. We humbly hope that they may not be disappointed.

Any thing more grossly barefaced we never witnessed, than the conduct of the concocters of this Bill. At a period when a certain degree of liberality, real or pretended, is deemed absolutely essential for the character of every public

measure,—destitute of common decency, the persons in question cry out for a narrow and illiberal enactment, vile enough to disgrace the code of the least civilized people in Europe: and while they seek to secure to themselves this flagrant monopoly in their own country, they are modest enough to be ambitious of the additional privilege of becoming general practitioners in England.

The question whether these persons of the Irish College are competent to the functions of an English apothecary, is quite distinct from the subject of which we treat. Of course, if the legislature choose to ordain that the *English* surgeon may, if he please, become an apothecary, we, in the spirit of the liberality which has ever characterized our arrangements here, have no objection to the admission of Scotch, and even *Irish*, surgeons to the same privilege; but first we must be satisfied on what grounds the latter class assume to themselves the right of monopolizing every thing in their own country, and then, not content with their chance of procuring *surgical* appointments here (from which they have never been excluded), would fain be eligible as general practitioners also. Let it not be forgotten, that, as matters now stand, the English surgeon is not only ineligible to a County Infirmary in Ireland, but the English apothecary also is excluded from exercising that branch of the profession for which he is, on all hands, acknowledged to be so perfectly qualified!

We have often had occasion to notice the presumptuous forwardness of the Irish College of Surgeons: never, however, so seriously as now. We have often demanded who are the wonderful surgeons, springing from the Irish College, that entitle it to such peculiar immunities; and we have never had the shadow of a reply. If it can be shewn to us that the system pursued in the York-Street College is superior to that

of all the other Colleges in the Empire—if it can be shewn that their diplomatists are superior to those of other places—then let these pre-eminent persons possess the peculiar advantages to which their superior qualifications entitle them, and let us hold out encouragement to such ornaments of the profession to come and settle amongst us. But as we have never been favoured with the least proof of this superiority, and as we have long since made up our minds as to the average merit of the individuals in question, we see no reason for conceding to *them* any peculiar indulgence; and the more so, as, in the instance above quoted, their grasping and graceless conduct disentitles them to all favour and affection.

There is one other feature in this new Irish Infirmary Bill which is curious—namely, the prominent position which the medical men of the *Meath Hospital* have in it. This, together with the active part taken by the surgeon *en chef* of that establishment, during his recent visit to London, in procuring the measure a first reading in the House of Lords, marks pretty distinctly the paternity and place of birth of this jobbing Bill. Only think of the special privilege aimed at by the men of the Meath! In all the contemplated Infirmaries throughout Ireland, the surgeons are to be elected (always with the *exclusive* proviso) by the governors and annual members, except in the Meath Hospital alone, where the surgeons and physicians are to be *self-elected*. It is to be made lawful for them, or a majority of them, to elect a physician or surgeon, in the room of any physician or surgeon who shall make a vacancy in the hospital. And what does the reader think, do these specially excepted, self-privileged, individuals give up by way of a set-off for the precedence which they thus assume? Why they give up their joint claim to the hundred a-year,

which would otherwise be divided amongst them!—as the Bill says—“in consideration of their relinquishing, on behalf of themselves and their successors in said hospital, all claim and title to the annual salary of one hundred pounds of the public money, which they would otherwise be entitled to, in consequence of this Act.” Wonderful disinterestedness! Pure patriotism, thus to save the nation one hundred pounds a-year; merely securing, in return, to the gentlemen of the Meath Hospital the trifling little privilege of making whom they please their colleagues!

But in our opinion, patriotism and disinterestedness apart, the faculty of the Meath, with their enlightened *General* at their head, will have richly earned much more than the sum which they forego, by their cleverness in getting up this Bill in behalf of the diplomatists of the Irish College; and we should certainly add, that the said College ought to see that their worthy managers suffer no detriment in their finances in consequence of such disinterestedness, did we not recollect that those persons are themselves, for the most part, the staff of the establishment, and sure of reaping a rich harvest if the measure be carried!

Of the dexterity of the Scotch managers in slyly getting up *their* Bill, we have before had occasion to speak; but we had then no idea how soon our campy friends in the North were to be eclipsed by our modest friends in the West. For gross jobbing, and cool effrontery, considering the party from whom it emanates—the *reciprocity* seekers—we are disposed to think that this new Infirmaries' Bill has scarcely ever been equalled.

In another page we give an abstract of its contents; and it is almost unnecessary to add, that we shall watch narrowly its meanderings through the legislature.

SCOTCH APOTHECARIES' BILL.

WE have to announce that the Bill, as it could not be carried through in its original integrity—to accomplish which a great effort was made in the Committee—is withdrawn. The Scotch College of Surgeons is not content to be placed on the same footing as that of London, and the result will be a general inquiry into the state of the medical profession next season: a happy issue of an unpromising commencement. Copies of numerous petitions against the Scotch Bill have been forwarded to us, but we do not now think it necessary to insert them. We take some credit to ourselves for having stirred up the profession to an expression of their sentiments, and can positively state that it was the demand for a general, instead of a partial measure, coming to parliament from so many quarters, in the shape of petitions, as recommended in the pages of the *Medical Gazette* some weeks ago, which has led to the removal of a threatened evil and the prospect of future inquiry; and we therefore trust of fair and impartial legislation. By the way, we ought to mention, in reference to our remarks last week regarding the College of Surgeons, that we are informed the Society of Apothecaries did stipulate for, and the College of Surgeons (after due deliberation) had consented to, the addition to their curriculum, of attendance on medical practice; which provision was to have been introduced into the Bill when in Committee.

MALIGNANT CHOLERA.

SEVERAL cases of cholera, presenting all the characters of the epidemic of last year, have occurred in London within the last fortnight; without, however, as yet manifesting any strong disposition to spread. It is proper for

medical men to be aware of the facts, but we do not wish to excite popular alarm by indicating the particular situations in which the disease has appeared, farther than by stating that they are generally the same as last summer.

ALDERSGATE-STREET DISPENSARY.

AN appeal has been made, by the medical officers of this institution, to the general body of the Governors, against a proposal recently brought forward, of altering the rule with regard to elections. At present, no one can vote on such occasion unless he have been a Governor during six months. It has been recently recommended by a Committee, that, for "six months," the words "three days" be substituted. If this be adopted, the election will always be in the hands of the man, who has the longest purse, without any reference to his qualifications. We trust that the Governors, in justice to themselves and the public, will reject so injurious a proposal. The question is to be decided on the 10th instant.

ABSTRACT

OF

THE INFIRMARIES' (IRELAND) BILL.

*Ordered to be printed by the House of Lords,
10th June, 1833.*

1. THE preamble states, that it is expedient to amend certain former Acts relating to the erecting and establishing public Infirmarys and Hospitals in Ireland, in order to their amendment and consolidation. Those Acts are enumerated.

2. The Archbishop of the province, the Lord Chancellor, the Bishop of the diocese, and the Rector of the parish, are to constitute a perpetual corporation for establishing infirmaries in the several counties of Ireland. The Meath Hospital *par excellence* to be the County of Dublin Infirmary.

3, 4, and 5. These clauses state the qualifications for governors and annual mem-

bers, and the corporate privileges they are to possess.

6. In case of a vacancy, notice of an election is to be given in two *Dublin* newspapers, twenty-one days before it takes place, and "no person shall be capable of being elected a surgeon of any of the said respective county infirmaries or hospitals, who shall not previously have obtained letters testimonial of his qualification under the seal of the Royal College of Surgeons in *Ireland*; and that no other qualification or examination shall be necessary to make any person capable of being elected surgeon of any such infirmary or hospital; and that no person shall be appointed physician to any such county infirmary or hospital, who shall not be examined and certified to be duly qualified under the seal of the King's and Queen's College of Physicians in *Ireland*."

7. This clause provides for the medical men of the Meath being self elected, while in all other county hospitals the members of the corporate body, namely, the governors, &c. are to elect.

8. One hundred pounds annually to be paid to the medical attendants of each infirmary, as specified.

9. The Grand Jury empowered to present to the amount of 600*l.* annually, for the support of the said infirmaries respectively.

10. Certain additional infirmaries may be built in each county, under certain conditions.

11. The Grand Jury may present an additional 100*l.* to the medical attendants.

12, 13, 14, and 15, are clauses relating to minor arrangements, such as quarterly and other meetings of governors, &c.

16. Restricts the apothecary in each infirmary to be a person certified by the *Irish* Company of Apothecaries, otherwise not to be entitled to his salary of 30*l.* a year.

ON GONORRHOEAL OPHTHALMIA.

By BARON DUPUYTREN.

From the "*Leçons Orales*," published periodically, under the Baron's inspection.

THERE are few weeks, said M. Dupuytren, during which cases of venereal ophthalmia do not present themselves, either in the wards or in the consultation-room. This severe affection most frequently results from a direct inoculation by means of the fingers applied to the eye, when soiled by the mucus of the urethra. In some cases, however, the ophthalmia appears on the sudden suppression of a urethral discharge, particularly when the

cause of this is at the same time calculated to affect the conjunctiva; for example, exposure to cold. M. Boyer says that this disease is extremely rare in women; but this assertion appears to me to be inaccurate: in hospitals devoted to syphilis, we see many more ophthalmic cases in women than in men, and the wards of the Hotel Dieu present a similar result. But, however this may be, the affection is always very troublesome, and requires constant attention and energetic measures on the part of the medical attendant. The inflammation has been known to destroy the ball of the eye, and empty it in seven or eight days. You saw, a short time ago, two women who speedily lost their sight in consequence of gonorrhoeal ophthalmia. A child, who is at present (April 1833) in one of the wards, also became blind from the same cause. In these three, the disease was not treated from the commencement, so that they had nearly lost their sight when they came to the hospital — examples which unite with many others in proving that too much precaution cannot be adopted in preventing so terrible a result.

It is generally said, that when the ophthalmia results from suppression of the discharge from the urethra, it affects both eyes* at once, whilst that from inoculation only attacks one. Actual observation seldom confirms these distinctions made in the closet, and in most of the cases I have seen, and almost all of which depended on the latter cause, both eyes were equally affected. In these different cases, however, be the cause of the ophthalmia what it may, the most energetic means must be promptly adopted to obviate the consequences.

Antiphlogistics, such as general and local bleeding, emollient lotions, and revulsives of every kind, are generally insufficient. Without neglecting these means, which are without doubt advantageous, it is necessary to have recourse to a local and special treatment, the others being in reality but accessories. This treatment consists in the insufflation, by means of a small tube, of calomel, prepared in vapour, on the conjunctiva and palpebræ. This insufflation is to be repeated once or twice daily; and one or two drops of the liquid laudanum of Sydenham are to be introduced between the eye lids, but only in the evening.

CASE I.—*Gonorrhœal Ophthalmia of ten days' duration — Employment of Insufflation of Calomel — Restoration of the left Eye.*

I.—, aged 30, a very fat little mar-

* In the original it is "*les deux sexes*," but the context shews that this is a misprint, *eyes* being evidently meant.—*Translator.*

chandé, enjoying good health, who menstruated at 14, and had in very short time six children, none of whom she suckled—had suffered much from leucorrhœa, and been much exposed to the weather. This woman had had several attacks of discharge from the vagina. She states that from the 18th to 20th of January the cold air greatly incommoded her eyes, and that they were inflamed. On the evening of the 20th, the right eye became the seat of acute pain, as if filled with sand; she could not sleep, and next morning the eyelids were so much swollen that they could not be separated. She was ordered cataplasms, the hip-bath, and a lotion; but without benefit.—On the 22d a large blister to the arm. On the 24th the left eye similarly affected. Same plan of treatment pursued till February 2d, when she was brought to the Hôtel Dieu. The eyelids were then much swollen, the conjunctiva forming a projection of a deep red colour, very painful, and with a greenish, puriform, very offensive discharge. The cornea could not be seen, the patient could not distinguish any object, and had constant deep-seated shooting pains of both eyes, with headache, anorexia, and fever. She had a very abundant discharge from the urethra and vagina, regarding the origin of which she would give no information, but the appearance of which spoke for itself; and in these cases the answers of the patients add little to the conviction of the practitioner.

In the evening the insufflation of prepared calomel between the lids was commenced, and a drop of laudanum instilled into each eye. The parts were washed carefully with plain water, and the eyes protected by a bandage. She had a better night.

Next day the same means were continued, the insufflation being performed night and morning with the greatest care. The barrel of a quill or a small glass tube was made use of, into which a little powdered calomel was introduced, and then the eyelids being held apart as much as possible, the breath was applied at the other end of the tube, and the powder blown over the whole of the diseased surface. In such cases the movements of the eyelids and the tears, which flow in abundance, carry the remedy into every fold of the conjunctiva.

Under the use of these remedies the improvement was rapid, the purulent discharge diminished, and the pains became much less acute. Nevertheless the tumefaction of the conjunctiva had not diminished sufficiently to admit of the cornea being seen, so that it was impossible to

say as yet what the termination of the case might be. Neither must it be forgot that the disease had existed more than ten days before the patient came to the hospital. It is not improbable, therefore, that ulceration of the cornea may take place, leading to the loss of sight.

At the end of fifteen days the left eye had regained its functions.

CASE II. — *Gonorrhœal Ophthalmia—Early adoption of the Treatment—Speedy Recovery.*

A woman, about 25 years of age, came, a month before the preceding, to the Hôtel Dieu, to be treated for gonorrhœal ophthalmia of the right eye. A green-coloured pus bathed the lids, and the eye could not be opened without great difficulty. The conjunctiva was much swollen, and the pain very acute. The insufflation of calomel and the use of the laudanum were begun five days after the onset of the disease; a sensible improvement was remarked some time after the commencement of the treatment; by degrees all the symptoms disappeared, and in three weeks she was quite well.

Gonorrhœal ophthalmia is frequently met with in children, and it is then generally called puriform, without any particular reference to its cause. It depends, in new-born infants, on direct inoculation which has taken place during parturition. It is always severe, and often leads to the loss of the eye. The treatment ought to be the same as for adults, and much care is required and much perseverance, because the pain produces a spasmodic contraction of the orbicular muscles, so that it is very difficult to introduce the remedies effectually.

Those who have attended the Clinique of the Hôtel Dieu for some years, have seen a considerable number of persons affected with gonorrhœal ophthalmia under treatment, but have never witnessed any attempt made to restore the urethral discharge. It is proper to remark, however, that as a too sudden cessation of such discharge may produce ophthalmia, so this is to be avoided. In most cases, however, the two proceed simultaneously, without apparently influencing each other as revulsives. The idea of antagonist affections, so seducing in theory, is rarely in accordance with facts. Inflammation of the skin frequently produces similar affections of the mucous membranes; those of the serous membranes produce, it may be, the successive development of one serous inflammation after another; so that analogous structures are, in fact, much more in accordance than those which are dissimilar.

Veneral ophthalmia naturally leads us

to speak of some other affections of the eye; the treatment of which, though they be different as to cause, is worthy of attention, on account of its efficacy.

Specks on the Cornea.

During some years, patients have come to consult me about specks on the cornea, as they used formerly to consult Desault for chronic ophthalmia, whether scrofulous or otherwise. The treatment I employ consists in the following methods:—If the irritation is acute, I have them bled; if it be less considerable, leeches are applied to the temples. I then administer one or two gentle purgatives, at the distance of two or three days from each other. A seton is introduced into the back of the neck; and a cylindrical one, made of cotton, is preferable to those which are flat. To these means I add the insufflation, night and morning, of a pinch of the following powder—viz. tutty, candied sugar, calomel prepared in vapour; of each equal parts. The eyes are neither to be washed nor rubbed after the insufflation;—when there is no disease of the eye-lids, no inflammation, no irritation of the conjunctiva, the insufflation of the above powder is generally sufficient of itself to remove the specks. Those which are recent and slight, are completely dissipated in some weeks. Specks of a longer standing, thicker and broader, usually disappear in a month or six weeks; and I have seen some, which occupied nearly the whole cornea and obstructed the entire pupil, completely intercepting the light, disappear entirely in the course of a few months.

Inflammation of the Retina.

This affection produces long-continued and obstinate pains in the head—contraction of the pupil—turbidness of the aqueous and vitreous humours—redness of the conjunctiva—constant flow of burning tears—intolerance of the smallest light—strong contraction of the orbicular muscles—the formation behind the pupil of a fibrous pellicle, to which the iris becomes adherent. This inflammation, which very frequently attacks scrofulous children, and is characterized by horror of light, may no doubt be treated by bleeding, leeches, purgatives, setons, &c.; but experience has too often convinced me of the insufficiency of these means, and has consequently led me to seek for others. That which during ten years has succeeded best, is the internal use of the powder and extract of belladonna. I prescribe the former in the dose of three, four, eight, twelve, or more grains; the latter in that of one, two, three, or more grains; either being divided into six doses,

and one taken every two hours. To prevent narcotism, either local or general, such as this remedy might occasion, I am in the habit of accompanying its exhibition by the use of artificial Seltzer water.

It is unnecessary to say, that *antiscrofulous* and *antiscorbutic* remedies can only increase the inflammation.

MIDDLESEX HOSPITAL.

Dislocation of the Humerus backwards on the dorsum of the Scapula.

DISLOCATION of the humerus backwards is so rare that Dessault never met with it; and his editor, Bichat, declared that no instance of its occurrence was recorded, implying a doubt of the fact itself. In this respect Bichat was wrong: amongst others, Kirkland saw and reduced two cases of it. Boyer was formerly of the same opinion as Bichat, having remarked that “there is one species of dislocation of the humerus which, though described, and the possibility of it made manifest, we are not acquainted with a single instance—it is the dislocation outward or backward.” But further observation has shewn this experienced practitioner one example of this dislocation; and Sir A. Cooper has met with it only twice in the course of thirty-eight years practice.

An instance of this dislocation lately occurred at the Middlesex Hospital, in the person of Mary H—, æt. 49, of spare make, who presented herself on the afternoon of June 4th, shortly after an accident which had disabled her right arm. Mr. Gill, the house-surgeon, having recognized the nature of the accident, called the surgeon of the week, Mr. Arnott, who happened to be in the hospital at the time, that he might have an opportunity of witnessing the unusual occurrence.

The nature of the injury was evident to the eye, without the aid of the sense of touch. The projecting head of the humerus was seen on the dorsum of the scapula immediately below its spine, with an excavation in front, under the acromion, in the natural situation of the joint. The arm hung by the side precisely as the left or sound one, and was not directed forwards and outwards, as represented by some writers in describing the symptoms of this dislocation. The head of the bone could be made, and was seen, to rotate in its new situation on the back of the scapula.

The accident occurred in the following way:—The patient was reaching down a box from the top of another which stood on a bedstead. In doing this her arm was

extended upwards and forwards, the hand being placed so as to receive the box, when this suddenly slipped off the other, and she felt her right arm give way and fall powerless by her side, the box at the same instant coming to the ground.

The reduction was thus effected:—The patient was seated on the ground, with the sound side close to a wall, in which was a staple on a level with the shoulder, to which the apparatus for fixing the trunk and scapula was attached. Extension was made by two men by means of a cloth attached to the humerus, the direction of which was outwards, forwards, and a little upwards, the surgeon standing behind the patient, and retaining the scapula from yielding forwards. After hanging on for some time, and then by a more forcible extension, the head of the bone slipped into its socket with a snap.—An effort at reduction by one man on the towel had previously failed.

ROYAL INSTITUTION.

New Law of Electrical Conduction.

DR. FARADAY, having had a paper of his read on this subject at the Royal Society last night, undertook to give a popular account of it here this evening. The law in question relates to the conducting power which bodies acquire upon undergoing a change from the solid to the fluid state. This fact is most obvious, as it was first observed, in water, which, the moment it is frozen, becomes a perfect non-conductor. The same holds good of the oxides, chlorides, salts, &c., which in the solid state are non-conductors, but upon being liquefied become conductors, and are decomposed by the electric agency. Water, however, is not to be considered as essential to electro-chemical decomposition; for the truth is, that water is nearly the worst of all conductors decomposed by the battery. The popular, but erroneous impression to the contrary, owes its origin, no doubt, to the observation, that of bodies decomposable when fluid, water is the only one having that property at ordinary temperatures. Dr. F. noticed also the relation which bodies, affected by this law, have in respect to heat and electricity. When solid they conduct heat, but not electricity; when fluid they conduct electricity, but not heat; and the difference of a single degree of heat is sufficient to take away one power and give the other, and

that without the slightest change in their chemical composition.

Friday, May 31.

On the Circulatory System, especially of the Lower Animals.

DR. GRANT delivered a very interesting lecture on the development of the vascular system in man, and the correspondence of its several stages with the permanent condition of that system in the lower animals. He commenced with a brief allusion to the well-known gradations in the development of the osseous and nervous systems, and proceeded to shew a similar gradation in the vascular. For this purpose he explained, by a series of well-executed diagrams, the plan of the circulation from the lowest to the highest creature in the scale, and concluded by pointing out the several phases of the development of the heart and great vessels in the human subject, contrasting each with the permanent condition of the same organs in the lowest classes. The contrast was rendered particularly striking by the diagrams, which we learned were from the pencil of Dr. G. himself.

On Friday evening, June 7, Mr. Palmer gave a lecture on the laws which regulate the disposal of shingle and shells on the sea-beach—a curious subject, but not very clearly treated.

And on the Friday after, June 14, the evening meetings closed with an interesting lecture from Mr. Brockedon,

On Caoutchouc, its uses, and more particularly its application to the Manufacture of Elastic Web.

The natural history of caoutchouc, its source as procured from various plants, but especially from the *Iatropa elastica*, were treated of in the first part of the lecture. The applications of the substance to different uses—such as the elastic balls for playing with, and some of which had been extended to the enormous size of four and five feet in diameter—the air-cushion—the water-bed, were then noticed. After which Mr. Brockedon described the machinery by which caoutchouc is made into thread. To such a degree of tenuity may it be drawn, that a single pound weight will yield 8000 feet of a thread, technically called No. 5, which again by machinery may be divided in length into four threads, thus giving 32,000 feet of thread from a pound of elastic gum. From threads of this sort used as a warp, a cloth or web is woven, which has been already applied to multitudinous uses, such as girths and

rollers for horses, bandages in surgery, &c. &c. However unyielding it may be at any time, the application of a hot iron renders it instantaneously extensible, even to an almost incredible degree. The different solvents of caoutchouc were enumerated, and the manufacture of water-proof cloth described; and finally a fluid (the composition of which is a secret) was used, by means of which the thread, however apparently rotten, was immediately renovated, and restored to even more than pristine elasticity.

EXCEEDING MINUTENESS OF CERTAIN ORGANIZED BEINGS.

SOME idea may be formed of the high degree of attenuation of which organized matter is susceptible from the following facts. By Professor Ehrenberg's measurement, the *monas termo* does not exceed 1-1500th to 1-2000th of a line in diameter; and he states that the four stomachs do not occupy half the bulk of the animal: each stomach must therefore be about 1-6000th of a line in diameter. Some of Professor Ehrenberg's observations tend to prove that the genus *monas*, and some others, are only the young state of some *kolpodæ*, *paramaciacæ*, &c. But supposing them to be perfectly developed animals, and that their ova bear the same relation to the size of their bodies which those of the *kolpodæ* do—that is, 40 to 1—we must conclude the existence of young monads which have a diameter of only 1-60,000th of a line, or 1-720,000th of an inch. Each of these monads must possess a stomach and organs passing in dimensions the power of numbers, and certainly giving us very boundless ideas of the wonders of organized nature.—*Amer. Jour. Med. Sc.*

CHARTER FOR THE GOWER-STREET SCHOOL.

MR. TOOKE brought on his promised motion on this subject last night (Thursday), but withdrew it again, without venturing to divide the House, in consequence of an announcement from Lord Althorpe that the matter has been for some time under the consideration of government. There seems to be some likelihood that a charter may be granted to this school, but certainly not with a greater extent of power than that possessed by King's College: we mean that the Gower-Street School may be incorporated, but shall not have the privilege of conferring degrees.

Kept at EDMONTON, Latitude 51° 37' 32" N.
Longitude 0° 3' 51" W. of Greenwich.

June 1833	THERMOMETER.	BAROMETER.
Thursday . 20	from 45 to 63	29.86 Stat.
Friday . . 21	39 71	29.87 to 29.92
Saturday . 22	41 68	29.92 29.81
Sunday . . 23	39 62	29.58 29.47
Monday . . 24	43 61	29.54 29.69
Tuesday . . 25	49 62	29.76 29.85
Wednesday 26	43 65	29.83 29.70

Prevailing wind S.W.

Generally cloudy, with daily rain. Several peals of distant thunder during the afternoon of the 24th. The whole week unseasonably cold.

Rain fallen, .575 of an inch.

Thursday . 27	from 43 to 66	29.62 to 29.74
Friday . . 28	41 71	29.83 29.86
Saturday . 29	39 72	29.86 Stat.
Sunday . . 30	39 71	29.84 29.75
July.		
Monday . . 1	39 67	29.70 29.83
Tuesday . . 2	41 70	29.85 29.92
Wednesday 3	44 71	29.97 30.02

Wind variable, S.W. prevailing

Except the 29th ult., the 2d and 3d inst., generally cloudy, with frequent and at times heavy showers. A peal of thunder in the afternoon of the 1st instant.

Rain fallen, .1 of an inch.

CHARLES HENRY ADAMS.

MIDDLEMORE ON THE DISEASES OF THE EYE.

We understand that Mr. Middlemore has in the press a work on the diseases of the Eye. From the known abilities of this gentleman as an ophthalmic surgeon, and the author of the excellent lectures on the Eye recently published in this journal, we should anticipate very favourably of his new work.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE ABDOMEN.

—
DISEASES OF THE LIVER.

WE will now proceed to consider diseases of an organ far more important—namely, the liver. The liver is very subject both to acute and chronic inflammation.

HEPATITIS.

Acute Hepatitis—When the liver labours under acute inflammation to any amount, the symptoms are pyrexia and constant pain, chiefly in the right hypochondrium. The greater part of the liver is on the right side, and therefore you have the pain chiefly there. There is likewise a sense of tension, or weight. It is said, that if the surface of the liver suffer, you have mere tension; whereas, if the substance be affected, then a weight is experienced; or if it be the peritoneal coat which is inflamed, then you have a greater degree of pain on pressure, and pain of a sharp character. The pulse is said to vary accordingly as you have inflammation of the peritoneal coat, or of the substance; but you cannot depend much upon that. You have different kinds of pulses under various circumstances. The pain extends up to the scapula, goes through likewise to the back, and very frequently to the right shoulder. The patient lies best on the right side, and for this reason—if he lie on the left, the whole mass of the liver, situated as it is chiefly on the right side,

drags towards the left, and all the parts are put on the stretch. You find, in disease of the heart, that he lies best on the right side, and this is also the case in disease of the liver; but the situation of the uneasiness makes the difference very remarkable. There is difficulty of breathing and affection of the chest, but not so great as in disease of the heart. The difficulty of breathing of course arises from the movement of the liver in respiration, according to the ascent and descent of the diaphragm. There is likewise, from the proximity of the liver to the diaphragm, a dry cough; and if you have any doubt about the situation of the pain, whether it is just on one side the diaphragm or the other, you have only to apply the stethoscope; and if it be disease of the liver, you find no alteration of the sounds, whereas, in an affection of the chest, you will find the various signs which I mentioned before. From the proximity of the liver to the stomach, there is very frequently nausea and vomiting; very often there is a little jaundice, and sometimes complete jaundice.

This acute inflammation frequently terminates in resolution, and sometimes in suppuration. The latter circumstance is rare in this country, but in hot climates it is very common.

Abscess of the Liver.—Occasionally, as you will recollect I mentioned when speaking of suppuration of the brain, the pus is secreted in small drops throughout the organ; but in other cases it forms one immense abscess, and sometimes both circumstances occur. The quantity of matter which will be collected in this way is sometimes enormous.

Now there are various ways by which nature gets rid of this pus. Occasionally an adhesion forms between the two parts of the peritoneum—the loose and the visceral—and the matter points externally. Sometimes an adhesion takes place to the stomach, sometimes to the intestines;

and I think the matter more frequently finds an outlet that way than any other. Sometimes nature does not succeed in forming adhesions, and then the matter is poured into the peritoneum. Now and then a less favourable occurrence takes place than the discharge into the stomach and intestines—adhesions take place to the diaphragm, and the matter is discharged through the air-passages. We have cases on record in which the pus has discharged itself into the gall-bladder, and still more rare cases in which it has been presented at the back—not at the front or at the side, but at the back; and cases of this description have been mistaken for lumbar abscess. Occasionally the matter has been discharged with the urine; and there is one case upon record in which an abscess emptied itself into the vena cava, and death was the consequence. Sometimes the abscess does not discharge itself at all, but there it remains; and patients have died with a large abscess in the liver, the existence of which was not known before. Of course if the matter be disposed to discharge itself externally, it is evident enough: if it discharge itself into the stomach you have vomiting of matter; if into the intestines, you have a quantity of matter in the stools; and if it discharge itself by the air-passages, you have cough and many of the signs of phthisis.

Termination in Chronic Hepatitis.—But perhaps more frequently than not, the acute disease subsides into the chronic form. If the inflammation be situated on the surface, you will have great chronic inflammation—you will have great pain there, especially on pressure, and in all probability ascites, from the peritoneum being affected. If the substance only is diseased, and the peritoneum escapes, you have mere dull heavy pain there, and very frequently no ascites at all.

Common in Fevers of Hot Climates.—The acute form of the disease is very common in all the fevers of hot climates, and hepatitis is continually united with all other inflammations of the abdomen—with enteritis, peritonitis, gastritis, and all other inflammations of that part. The chronic form is very often united with dysentery: it is very common for a person to have chronic dysentery and also chronic hepatitis.

Chronic Hepatitis.—Of course you may have chronic inflammation of the substance and surface of the liver conjoined, the same as in the acute form; and the former, as well as the latter, will produce an abscess, and be followed by all the structural diseases to which the part is subject.

Cause.—The causes of hepatitis, whether

acute or chronic, are the common causes of inflammation—getting wet, exposure to cold, and all the rest of these things. It appears to be much predisposed to by continued heat; the disease, at least, is very common in hot climates. It is said that long-continued heat alone induces pure hepatitis; whereas, if the long-continued heat be united with the cause of fever—such as malaria and other things—then you have a combination of hepatitis with various fevers.

Diagnosis.—As to the diagnosis, the disease is easily distinguished from inflammation of the chest in the way I have mentioned—by the absence of all auscultatory signs, and by the situation of the pain; from there being nausea, vomiting, and dry cough. It is distinguished from gastritis by the situation of the pain, being much to the right side; while, in gastritis, it is in the epigastrium, and more to the left side, from the stomach being to the left of the epigastrium. You may have symptoms at the epigastrium, but you also have considerable pain on the other side. It is distinguished from peritonitis by the local nature of the pain: there is, in peritonitis, inflammation at other parts of the abdomen.

Treatment.—We have now to consider the treatment of acute and chronic hepatitis, and this may be dismissed in a very few words. It is the simple common treatment of inflammation, and for the most part it is very successful. You have only to make your diagnosis, and ascertain that it is disease of the liver, acute or chronic, and treat it accordingly.

I may mention, however, that it was once supposed (you will find it mentioned in works published 20 or 30 years ago,) that mercury ought not to be given in acute inflammation of the liver, because it stimulated the organ; but that it was proper in the chronic form. Now the truth is, both forms require the same treatment. The terms acute and chronic merely refer to the duration of the disease, and there is no difference, except that the symptoms are less urgent at one time than at the other, and whatever is good in the one is beneficial in the other in a less degree. But independently of that consideration, I do not know that mercury has any extraordinary power in stimulating the liver in the way it has been supposed. It was thought it would give a bilious tendency when there was not one, and it is possible that mercury will produce bilious evacuations when it is long continued; but I am sure that mercury pushed on to ptyalism is just as useful in active hepatitis as in any other acute inflammation. I do not know that it will do any good by its specific action on the liver, but by its

general tendency to subdue active inflammation. Purgatives are particularly useful in inflammation of the liver, much more so than in inflammation of the chest, as you may readily suppose; because they act as local means, and prevent a great quantity of blood going into the vena portæ, and therefore less goes into the liver.

The chronic inflammation requires the same treatment as the acute, only carried on less violently, carried on chronically—not doing all you have to do in a day or two, but carrying on your measures for some weeks, or even months. The moderate exhibition of mercury, not to produce a rapid ptyalism, but so as to keep up a gentle affection of the mouth, is useful.

Long continued purging is very beneficial in chronic disease of the liver, and hence the Cheltenham waters do great good in this affection, from draining the abdomen generally. Some have conceived that acids are useful as tonics, and nitric and muriatic acid were very famous sometime ago, but I do not know that there is any particular use in them. I have always succeeded in treating chronic inflammation of the liver, by the same means that I employ in any other inflammation—more or less loss of blood, general or local, and the moderate exhibition of mercury. I have never found it necessary to make any difference between treating inflammation of the liver, and the same disease in any other part. Some have thought that dandelion does good, but I have never seen its virtues in affections of this kind.

As to the suppuration which sometimes occurs, that requires to be treated on common principles. If the abscess point to the skin, of course a knife may be applied, and the matter let out, just as in any other abscess, only that it might be dangerous to let out a great quantity at once: it should be done gradually, that the part may slowly contract. If the discharge take place inwardly through the lungs, or the intestines, you have only to lessen the irritation by narcotics, as in other cases; and this will also be required if you open the abscess.

Structural Disease of the Liver.—Many diseases of the liver are called chronic hepatitis. The liver is subject to a vast number of structural diseases, and these pass as chronic hepatitis, and indeed it is very often impossible to make the distinction.

Symptoms.—You will find, at the outset, pain on the right side, pain at the shoulder, perhaps a little jaundice, tenderness in the region of the liver, feverishness, and wasting, and you may say that the patient is labouring under chronic hepatitis. You treat him accordingly, but find that you do not succeed; on the contrary, that the disease obstinately remains, and

at last the liver becomes, perhaps, much thickened, and very much enlarged. Sometimes from the very first it is enlarged and hardened, simply as the result of inflammation, and sometimes it may be subdued by the common remedies of inflammation. I am quite sure that the liver will, from mere turgescence of blood, inflame, and perhaps without inflammation, from mere congestion, it will become very large. I am sure that the bulk of the organ will alter according to the quantity of blood in it; for I have seen it large, and rapidly, in a week or two, it has been small again. I have no doubt that internal organs will vary very much; they will suffer, if I may so speak, a sort of erection from the congestion of blood; but certain it is, that the liver will sometimes be large from blood, and by active measures will come down in a very short space of time to the natural state.

But supposing that you have used the remedies for inflammation, and the disease does not cease, and the size of the liver does not diminish, then you have reason to suppose that there is something more than chronic inflammation—that there is a change of structure, and it is of no use to push on the means for remedying inflammation with activity; indeed you would only break up the constitution by them. It may be necessary, if there be pain and tenderness, occasionally to bleed, either by cupping or leeches; to exhibit mercury, and order low living; but if you push these things far, you frequently break up the patient's constitution without affording him any relief. It is often necessary to support the strength well, and even to give him stimuli, in order to enable the patient to bear up against this organic disease.

Diagnosis.—In regard to the signs of organic disease of the liver, you may sometimes make it out very well, by the edge of the liver being very well defined, running across, and being hard, and even sharp. You will sometimes find that the most easy way of discovering an indurated liver is not by pressing hard down around the region of the organ, but by putting your hand over it, and suddenly bringing down the fingers. Frequently the liver is an inch or two from the surface, and if you press it regularly you may not feel it, but if you press the integuments down upon it you feel it in a moment. Occasionally you may discover tubercles in the liver.

Treatment.—In all these cases it would be quite fair to have recourse to iodine, in the form of hydriodate of potassa, internally, and rubbed over the indurated part. I have seen large livers reduced by this means. I have seen livers reaching to the umbilicus, and below it, reduced by the

steady use of iodine, and sometimes iodine combined with mercury. But it is frequently necessary, while you are doing this, to support the patient well, especially if you exhibit mercury. Mercury should not only be given with caution, but you should support the patient well, because the dose that is necessary to do good tends to impair the constitution: iodine, however, may be made to do good without injuring the patient. Setons may, perhaps, be serviceable.

This is the general treatment of diseases of the liver, and we will therefore now speak of the *post-mortem* appearances.

Post-mortem Appearances.—On examining the liver after it has been in a state of common inflammation, you will find that it is the peritoneal convex portion of the liver that is generally inflamed. There may be red points, lymph, and turbid serum upon it, and the peritoneum may perhaps be thicker than it should be. In chronic inflammation you will find adhesions, and the bands are very strong. Sometimes on the surface of the liver you will see white patches, and the peritoneum will become white, opaque, and soft. If the substance have been inflamed, there is usually a general redness, and the size is increased from the quantity of blood it contains. Sometimes the redness is only partial, and then the liver looks almost mottled. When the redness is only partial, then the red plates, mingled with the parts naturally pale, give it a mottled appearance. In cutting the liver, generally a large quantity of blood flows out, and you must remember that without inflammation the liver frequently suffers a great congestion of blood. In the disease called *purpura* there is great congestion of blood in the liver. After asphyxia, chronic bronchitis, all disease of the heart, and all obstructions to the course of the blood through the heart or lungs, you will find the liver in a great state of turgescence, so that when you cut it the blood pours forth, and the vessels look like sinuses. In infants who have been asphyxiated at birth, occasionally the congestion of blood in the liver is so great at that portion under the peritoneal coat that sometimes it will burst through it into the abdomen. Sometimes in inflammation of the liver there is hæmorrhage into the substance of the organ, and sometimes the blood will rupture the substance of the organ. I presume there has been some degree of softness of it previously. You may find a great mass of blood, or several little collections of it; sometimes it is coagulated, and sometimes not; occasionally you may find it in the vessels, and sometimes not, accordingly as it has oozed from one or several.

CHRONIC DISEASES OF THE LIVER.

In regard to chronic disease of the liver, you of course recollect that the liver consists of two parts, the one sanguineous and red, and the other, like the kidney, white or yellow, containing bile. They are not divided, but there are two constituent parts throughout the liver lying in juxtaposition. Now sometimes it is only the red portion of the liver that it is hypertrophied, so that the organ is enlarged and red, and sometimes the biliary portion; the bile-tubes are all in a state of hypertrophy, and then you have a pale liver—a liver enlarged and pale. Sometimes, without being enlarged at all, it will be pale. The red part is atrophied, the vessels shrink, and the biliary part is hypertrophied; if not hypertrophied, indurated; if not indurated, it remains as it was; but as it bears a preponderance to the red portion, the liver looks pale.

Now these changes sometimes occur throughout the liver, and sometimes only in spots, so that you have one portion of the liver perhaps firmer and redder than it should be here and there; and in other instances you have the biliary portion hypertrophied here and there, giving it a mottled appearance.

Gin Liver.—Sometimes the hypertrophied portion gives you the appearance of white lines running along it, and sometimes of granules, varying in size from pin's heads to hazel-nuts. Now there is a difference of opinion among morbid anatomists in regard to this, which was called *gin liver*, and which is the most common of all organic diseases of the liver. Dr. Baillie and others suppose that they are minute yellow tubercles throughout the liver, and Andral imagines that it is a mere hypertrophy of the biliary portion. Cruveilhier has given a good delineation of this disease, and has called it small brown tubercle. I suppose, as it is a *gin liver* in this country, it is a *brandy liver* in others; perhaps an alcohol liver would be the best name. It occurs in spirit-drinkers in one country just the same as in another: there is the same punishment for them all. I presume that the constant use of alcohol induces a chronic change of the biliary portion of the liver, causes it to become hypertrophied, causes it also to become indurated, just as any serous membrane will become, from other circumstances, indurated, opaque, and hard. This is the history of this particular matter.

You sometimes see this morbid change more in one lobe than in another; sometimes the liver is increased altogether, and sometimes, instead of its being increased, it is shrunk. The liver generally feels very hard on the external surface. Frequently

it is indurated in particular portions, but on the whole wasted. You find, I think, that in by far the greater number of cases a gin liver is of a bright yellow colour, and generally there is more or less of ascites. The peritoneum over the liver is generally more or less diseased: it is particularly opaque and hard.

Fatty Liver.—Perhaps the disease to which the liver is most liable is that of becoming fatty: the liver is sometimes exceedingly fat. You know that by nature the liver contains what is called *fat* and *cholesterine*, and these matters will sometimes exist in a great degree.

When the liver has degenerated into this fatty state, it is usually soft and flabby, instead of being indurated: sometimes it is greyish or whitish, and such is the portion of fat deposited that it greases your fingers. When you cut such a liver, or handle it, your fingers become greasy; and in those parts which are the most fatty, it appears as if there was no blood there at all. This disease, like every other, will of course affect the whole liver, or only portions of it. This state is frequently united with phthisis. It is a disease seen continually, without the person having been addicted to drinking, or having imbibed any bad habits. It occurs frequently in young persons.

Encephaloid Disease of the Liver.—The liver is also subject to encephaloid disease—to what is called *fungus hæmatodes*. This is much more rare than either of the other forms of disease to which I have adverted; but when *fungus hæmatodes* has existed in the extremities, then it is very common for a collection of this nature to take place in the liver. Occasionally, I believe, encephaloid tumors are said to be found in the liver without the disease occurring in other parts, but more frequently they are found in combination with disease of the extremities. These tumors are of course white, and there are tubercles sometimes producing an elevation on the external surface—bumps. They are of various sizes, existing some near to the surface, and some towards the centre of the organ; and when you cut them, you find they contain a brain-like substance.

Scrofula and Scirrhus of the Liver.—The liver is also subject to another disease—to a new formation, namely, scrofula. Scrofulous tumors take place from time to time in the liver, and they are of course white: the encephaloid tumors look exactly like them. Cruveilhier has given some good representations of them. The scrofulous disease is sometimes mixed with encephaloid matter—with brain-like substance, and sometimes there will be a mixture of scirrhus with it. I have fre-

quently seen in other parts scirrhus with scrofula deposited in the neighbourhood, and so it is in the liver.

Occasionally melanosis exists in the liver—the black deposit of which I formerly spoke.

These are the chief organic diseases of the liver. You will have besides inflammation, enlargement from congestion of blood, and abscess—the red part hypertrophied here and there, so as to give the organ a mottled appearance, and indurated at the same time, so as to give you red tubercles—tubercles, as it has been said in this country, but I would rather say tubercles; then you have the biliary portion hypertrophied, and that is called “gin liver;” in addition to that you will have encephaloid tumors, resembling the brain in structure, consistence, and colour, and perhaps with blood effused in them here and there; then you have scrofulous and scirrhus tumors, and melanoid deposit.

Size which the Liver may attain.—As to the size which the liver may attain, Mr. Gooch, a surgeon, mentions that he saw one which weighed 28 pounds. I have frequently seen it reaching into the pelvis. It is a curious circumstance, but you will sometimes meet with a liver thus enlarged, which has caused no suffering at all; the patient has never complained of pain, but has felt weak, and has wasted a great deal. This is the case particularly in women. I have frequently examined women in this state, who during life were not known to have disease of the liver; they never drew attention to the abdomen, but merely said they were weak. It shews the necessity, when you cannot understand the patient, of having them in bed, and examining them from the throat downwards, over the heart, lungs, and abdomen. In that way you will continually meet with something which was not in the least apprehended.

Hydatids of the Liver.—The liver is very subject to the formation of hydatids. The kidneys and the liver are the two organs of the body which are most subject to the formation of hydatids. The true animal nature of these hydatids has not, I believe, been pointed out in the human subject, though it has in sheep. In sheep they have been observed to have a contractile power; but this has not been noticed in human beings; the appearance, however, is so much the same, that one must suppose them to be real hydatids. They are sometimes within each other like pill-boxes; sometimes they are attached to each other by peduncles from within, hanging one within the other, and sometimes they grow to the outside of each other. You will see a representation of them in Dr. Baillie's work. Some-

times they are attached to the liver externally; they hang to it; but generally speaking they are enclosed in a cyst. Sometimes they are found in the middle of the substance of the liver. The cyst which contains them is usually hard, even cartilaginous. I believe they have some laminæ, two coats, and when they are dead they have no longer a globular appearance, but are like so many skins, or so much half-dried mucus. In sheep, I believe, they are seen to have a neck and a mouth.

I had a very remarkable instance of this description in a lady who had laboured under chronic hepatitis for fifteen years, and at last she began to cough and spit hydatids, and died. On opening her I found a large cyst of these hydatids attached to the concave portion of the liver, on the right side. In the middle of the liver there was another sac filled with them. Ulceration took place, and they made their way through the diaphragm, the cyst emptying itself partly into the air passages. Under all this the irritation was so great that she died.

Worms of the Liver.—Worms have sometimes been found in the human liver, and a lumbricus has been found in the ducts, but I should rather think it was a wanderer, that it was not a native, but that being on its travels from the intestines it lost its way.

Treatment of Structural Disease.—These are diseases of the liver in which you can do nothing more than treat the patient upon the common principles of inflammation, and endeavour to excite absorption by means of iodine and mercury, and support the patient's strength. As to the greater number of them, you cannot of course distinguish them during life. You can tell that there is organic disease, by feeling that the liver is very large and very hard, by the patient wasting away and becoming sallow and jaundiced; and sometimes you find there are tubercles, bumps in the region of the liver; but very often it is impossible to say what exact structural disease there is. If you have seen fungus hæmatodes, or scirrhus, in other parts of the body, you may suppose the disease to be of that nature.

JAUNDICE.

Etymology.—The next disease of the liver of which I will speak is one in which the secretion, instead of passing out properly into the intestines, is absorbed, enters into the blood, and tinges the skin and the urine yellow. I need not tell you that this disease, in common language, is called *jaundice*, which is derived from the French

word *jaune*; in brutes it is called the *yellow*; in medical language it is called *icterus*, from its likeness to the plumage of the golden thrush. You will find that in Latin it is termed *morbus regius*—the royal disease; and the reason given by several writers is, that persons require in this affection all sorts of amusements, that none but kings or royal persons can command. It is also called, in Latin authors, *morbus arquatus*—from the patient having the various hues of the rainbow. You will find it mentioned under another name—*aurigo*. I presume this has its origin from *aurum*—gold. The word *icterus* is said to be the name of the golden thrush; by looking at which, like the Israelites looking to the brazen serpent in the wilderness, those that have the disease are cured. You know that it was common, in ancient nations, for the cure of disease to be attempted by looking on certain things; and I suppose it had its origin from what occurred to the Israelites. The heathens fancied, when labouring under this disease, that if they looked upon the golden thrush, the bird would die and they would be cured.

The word *jaundice* is simple, and a very fine name for yellow. In the case of poor people it is called, in plain terms, the *yellow*; but if a lady have the disease, it is termed *jaundice*.

Symptoms.—This disease is marked by yellowness of the skin, yellowness of the eyes (the conjunctivæ), yellowness of the roots of the nails, yellowness of the urine, and paleness of the fæces. You may have this disease without the fæces being pale; but speaking of the symptoms generally, the fæces are pale. The parts which are first seen to be yellow are the nails and eyes, and they are the parts that remain yellow longest; simply for this reason, you discover in these parts, (in the half-moon of the nails, as it is called, and in the conjunctivæ of the eyes,) from their being naturally so very white, the slightest tinge of yellow. The yellow is not always of the same cast: you know that there is a bright, a dark, and a green yellow; and some persons labouring under jaundice are of a dark-olive colour, so that it borders upon green, and you therefore sometimes hear of *green jaundice*. If a person be naturally swarthy, when labouring under green jaundice he looks very dark, and then he is said to have the *black jaundice*; so that you have a green-yellow and a black-yellow. It is a contradiction of terms, but it shews the variety of hues under which the disease appears.

Yellowness of the vision.—Occasionally it has happened that patients have seen yellow. It was maintained by some that that was always the case. Dr. Pemberton says

that he saw this occurrence twice, and in both cases the jaundice was not very intense; on the other hand, you will every day see cases of intense jaundice, without any yellowness whatever of the vision. Hoffman says also, that twice he saw patients who declared that every thing appeared yellow. Now it has happened to me to have two patients labouring under jaundice, who made the same statement. In July 1826, I had a case of icterus in the hospital, where there was albugo of each eye, particularly of the left; and into this eye two large red vessels ran, and with it the patient saw yellow; but the right eye, which had no inflammation before the cornea, into which no large vessels were running, saw things in their natural colour. In 1827 I had another hospital patient who saw yellow with both eyes, and in him the conjunctiva immediately around the cornea, quite at the edge of the orbit, was greatly inflamed. I saw this morning a patient at St. Thomas's labouring under jaundice, who says that at the beginning of the disease he saw yellow. He does not know whether his eyes have been inflamed, but it is a fact that there are several pretty large vessels running not quite to the cornea, but pretty close to it. When patients see yellow, it is from the serum of the blood being conveyed before the pupil, through the cornea. It must be accounted for in that way. In the second case which I met with of this occurrence, I was prepared for inflammation of the eye by having noticed what I did in the first case. I looked carefully at the man's eye the instant he told me that he saw yellow, and I found, as I expected, that it was in a state of inflammation. Whether this will always be observed when patients see yellow, I do not know, but it affords an explanation of the circumstance, and is worth investigating. If a person labouring under jaundice is blistered, the fluid from the blister is yellow, and the serous fluids within the body are found to be of the same colour.

The blood loaded with bile.—It is worthy of remark, that the blood of jaundiced patients is loaded with bile. Hunter thinks that the artificial mixture of bile with the blood produces coagulation; but I think that a quantity of bile infinitely too little to affect a coagulation of the fluid, may nevertheless be sufficient to give a tinge to the serum.

Internal symptoms.—Besides these visible symptoms in jaundice, there are several others. You generally find patients complain of languor, and very frequently of drowsiness, but still more frequently they complain of a dead weight, a load at the epigastrium, and tenderness at the hypo-

chondrium, and sometimes of actual pain; in fact, this is a disease which every day occurs in conjunction with hepatitis, and is in many cases merely a symptom of it. There is frequently loss of appetite, nausea, and vomiting; and there is one curious symptom in the disease which is very common indeed, and that is an itching of the whole surface; people say they could tear themselves to pieces.

Occurs at all ages.—Jaundice occurs, like so many other diseases, both in young and old persons. Infants continually have it a few days after birth, and some perhaps at birth; and the oldest persons are liable to it. In infants it appears to be produced from the very slightest causes, and it is cured with the utmost ease. In general it is a slight disease, arising from slight causes, and may be cured by slight remedies.

Yellowness of the skin not always a symptom of Jaundice.—You will sometimes see yellowness of the skin not as the result of jaundice, but in fever, namely, that which is called *yellow fever*. The yellowness is not universal in this case; it occurs particularly about the neck, and it appears rather to arise from a disordered state of the blood, or an altered condition of the blood as to some of its constituents, exactly as we see it in bruises. You may have a person yellow from bruises. After a certain portion of blood has been absorbed from an ecchymosis, a degree of yellowness remains, but that is not jaundice; it appears to be produced from some portion of the blood being absorbed, and other portions left. Occasionally after the bites of certain serpents, and the infliction of wounds by the bite of certain animals, the skin will become yellow; but this does not appear to be jaundice.

Predisposing causes.—Some people would appear to have a constant predisposition to this disease; and it may be hereditary. Persons who have been in warm climates are much more predisposed to the disease than others.

Exciting causes.—The exciting causes of it are any thing which will produce inflammation and congestion of the liver; whatever will produce hepatitis, or cause great congestion of the liver, will produce jaundice. It will arise not only from cold and wet, and long-continued heat, but it will arise also from the suppression of a discharge by which a congestion of the liver will take place. It will arise from every thing which will cause even a mere excess of bile; for occasionally the fæces are not white in the disease. Bile passes into the intestines, but so much is secreted that all does not escape, and a portion goes into the blood. Malaria seems to have a ten-

dency to produce it in hot climates, and in the hot seasons of other climates. Persons exposed to the influence of malaria are very subject to have a degree of jaundice among them, and other hepatic affections.

Local causes.—It will be produced by a variety of local causes; any thing which will cause pressure upon the parts through which the bile is conveyed. Mere costiveness has been known to give rise to it. Tumors occasioned by an enlarged pylorus—by an enlarged head of the pancreas—tumors of the omentum—diseases of the liver (if a portion of liver becomes rather harder than it should be, and perhaps rather enlarged, the bile may be obstructed in the liver itself)—the lodgment of a calculus in the ducts, are also common causes of this disease. Sometimes pregnancy causes it. I have frequently seen jaundice in pregnancy; not, however, as the result of pregnancy, but of inflammation of the liver, and which went away under the treatment for common inflammation, while the pregnancy went on. It is supposed that it may be produced occasionally by thick bile; but if you do find the bile inspissated, there is no proof that that is the cause of the jaundice; for if there be any obstruction to the bile, of course by its continuance it will become thicker than it should be; and where parts are absorbed, the bile may be inspissated, but there is no proof that that is the cause rather than the effect of jaundice. It has been known to be caused by a lumbricus sticking in a duct of the liver. I mentioned when speaking of organic diseases of the liver, that a lumbricus has occasionally been seen which had lost its way and wandered into the liver, and if it stick there it may cause jaundice. If the ducts themselves become thickened by chronic inflammation—if they become hypertrophied—their canal may be so much diminished that the bile cannot easily pass, and consequently you have jaundice. I have seen jaundice from a great many of these causes; and in 1829 I met with a case in which it was occasioned by a great number of fatty deposits all around the ducts. Sometimes the ducts are impervious from original malformation: there are a few instances of this upon record. It would appear sometimes to be produced by spasm. I have known some persons, on eating certain articles, seized with violent pain at the pit of the stomach, and the next day an attack of jaundice has appeared. It has been produced by mental causes: many persons from fright have become yellow. I believe that in general people from fright look blue; but sometimes, from being exceedingly frightened, persons will have a fit of jaundice. Occasionally the disease

has arisen not from terror, but from long-continued grief and anxiety of mind.

Obstruction of the Ducts causes Enlargement.—When the ducts have been obstructed, they are generally larger than they should be; and Dr. Heberden is said to have seen them dilated to an inch in diameter. Sometimes, however, no obstruction is found. I have opened several persons who have died not from jaundice, but with it, in whom I could see no obstruction whatever; and Sir John Pringle mentions, in his work on Diseases of the Army, that one of the army surgeons told him of a case of jaundice in which there was no obstruction, but in which the slightest compression caused the bile to flow; and Andral, I find, says that he has seen the same occurrence.

Artificially induced.—Of course you may produce this disease artificially, by opening the abdomen and passing a ligature round the intestines, a little below the ductus communis choledochus. Portal has done this, he says, in six dogs, and they all became jaundiced. If you tie the lymphatic duct, the same circumstance will occur; and the absorbents of the liver have been seen, after such an experiment, to become loaded with bile.

Mode in which the Bile enters the Blood.—It has been said, however, that the blood from the lymphatic veins was found, in such an experiment, to stain paper yellow, much more so than the blood from the choledochus. There was a doubt at one time whether, in jaundice, the bile found its way to the blood by means of the absorbents or by regurgitation to the veins. A short time ago it was not supposed that the veins would absorb. Before the absorbents were discovered, it was supposed that the veins performed that office; but afterwards, no one allowed that they would absorb at all, and now again it is said that they do absorb. While it was believed that the veins did not absorb, some contended that in jaundice the absorbents took up the bile, and others contended that it worked its way into the veins. Experiments were then made, and it was observed that the absorbents of the liver were loaded with bile, and that the lymphatic veins were more tinged with it than those of the jugular. If the veins absorb as well as the absorbents properly so called, we may suppose that the greater portion of bile which found its way into the whole system of blood, having passed through the lymphatic veins, those veins would contain a greater portion of bile than any others.

Prognosis.—In regard to the prognosis of this disease, it must depend entirely on the cause. Jaundice is nothing more, in most

cases, than a symptom of some disease; and according to the nature of that disease must be the prognosis. Some are very ill in jaundice, and die *with* it; and others labouring under it go about with little indisposition—they scarcely know that they are ill, they only look very yellow. In that form of jaundice in which the yellow verges to green, and which has been called *green jaundice*, recovery is very rare. When you see an individual labouring under jaundice, who, notwithstanding his eyes are yellow enough, yet whose skin is of an olive hue, you may, without asking a question, fear that the individual has a disease from which he will not recover. Dr. Baillie says, that in the whole of his practice he never saw but two persons recover from green jaundice. Generally, where the jaundice is of this green hue, there is some organic disease of the liver—either of the whole or of a portion of it.

The disease sometimes lasts a very long time. The faces are in general white, but very often they are bilious. Dr. Baillie says, that in green jaundice the faces are usually white, as in other kinds of the complaint, but he has often seen them very pitchy. He says that there is but little pain felt, that there is seldom any ascites, and that he seldom knew it arise from intemperance; and the reason that he assigns for the latter circumstance is, that it so frequently occurs in women: some women, however, are intemperate enough. He considers it as a symptom of something which is fatal.

Dr. Cheyne mentions that the jaundice of children is dangerous if it be of a saffron hue. In children the complaint is generally trifling, but sometimes it is not. Mr. J. Pearson, a surgeon of great practice in London a few years ago, says that he knew a family where there had been eleven children, ten of whom died of jaundice within the month, the disease having begun a few days after birth, and that the eleventh died of the same disease at six years of age; evidently shewing the hereditary nature of the disease. What was the cause of it in this family, I do not know.

Treatment.—In the treatment of jaundice, you have first to consider whether any inflammation exist—whether it is a case of hepatitis; and if it be, you must treat it on the common principles of inflammation of the liver—in proportion to the weakness on the one hand, or the strength on the other. You will find that, in cases of jaundice, mercury answers better than any other purgative. I have frequently made experiments, and have exhibited common purgatives in some cases, and mercury, so as to affect the mouth, in

others; and I am sure that patients have recovered more quickly by the latter mode than by the former. In mild cases, however, where there is only congestion of the liver, the disease will yield to common remedies, and many cases will get well of themselves; but if the disease be more severe, it would be right to employ mercury, and perhaps to bleed in the arm.

The disease may be characterized more by spasmodic pain than by inflammation: there may be more occasional pain at the pit of the stomach, or on the right side, than constant pain and tenderness; and in that case the hot-bath and opium are among the best means. But in such cases as these, if you find the patient's pulse quick and strong constantly, one of the best antispasmodics you can employ is bleeding. If you find that the pain is not constant—that it comes on at intervals, and not with a constant severity—you may expect that the disease is to a certain extent spasmodic; and there opium and the hot-bath will be very useful: but if there be general tenderness besides, and bleeding is at all admissible, it will answer exceedingly well. It will be more effectual, and much better, to combine the opium with a full dose of calomel: this will prevent constipation, and produce a free discharge from the alimentary canal. In these spasmodic cases, in addition to the common treatment for hepatitis, you should give a large dose of calomel (ten or twelve grains), and a few doses of opium, perhaps two grains, or more. A poultice over the part is also very useful.

Now this sudden pain with jaundice is no proof whatever that the case is one of gall-stones. Many persons, where there is no jaundice at all, say that when a patient is seized with sudden pain at the pit of the stomach, they have gall-stones; and if, in addition, there be jaundice, then they consider the matter as certain. But mere spasm of these parts will produce this violent pain, and perhaps giddiness. You may suspect that there are gall-stones, but frequently you have all the symptoms without it; and you have no right to assert that a person has gall-stones unless you see them pass, or they have been discharged. When you consider, that from eating something which is indigestible, a person will be seized with violent pain at the pit of the stomach, and the next day will have an attack of jaundice, you see clearly that this occurrence may be produced without the presence of gall-stones; you see that it is obviously caused by something which has irritated the parts.

Chronic Jaundice.—You will find the greater number of cases of jaundice yield to purgatives, or to the treat-

ment for hepatitis; and if you find such severe pain as I have now mentioned, anti-spasmodic treatment will generally get rid of it; but the disease sometimes lasts a long time, becomes chronic, and it is necessary, after you find no more pain, no tenderness on pressure, to make the patient move about—to make him take free exercise, have the parts well rubbed, to recommend the use of the warm bath, and also to exhibit mercury so as to produce a mild affection of the month for a greater or shorter length of time, together with the free use of purgatives. When the disease has become chronic, it will frequently go away under the use of these means; the parts seem to fall into an atonic state.

Supposing that the affection continues in spite of all these means, then you will generally have reason to suspect that there is disease of the liver. If you find induration or enlargement of the organ, or a degree of ascites, or any kind of dropsy—if you find persons waste more and more, and especially if you find the tinge become green from having been the plain ordinary yellow—then you must form an unfavourable prognosis, and suspect disease of the liver. In the case of enlargement and induration it is pretty well proved, and then the remedies for diseased liver should be employed: setons over the part and the exhibition of iodine, will, of course, be the best means that you can employ, and you must keep up the patient's strength as well as you can.

With respect to chronic jaundice, there is a curious case which I stumbled upon in Van Swieten's work, where it was cured by making a man imitate Nebuchadnezzar. Van Swieten says that he persuaded a poor man, in an obstinate case of jaundice, to live upon grass for two years, except during that part of the winter when there was none to be got. He made him eat the tenderest grass, and also that which was first mowed; and he made him take that which was in flower. The man confessed that for some time this diet did but little please him, but after a time he was well contented, and could easily distinguish the best pastures by the flower of the grass (this I can imagine); and at last he became a general nuisance to the farmers, for they found he had so large an appetite that they drove him first from one field and then from another. This is Van Swieten's own account: he says he was obliged to eat his diet secretly; that the farmers finding he had so large an appetite, they often gave him a quick repulse. The man, however, was perfectly cured.

GALL-STONES.

It may be well to say a few words re-

specting gall-stones: we can do nothing to dissolve them, but when they are passing we may mitigate the patient's pain.

Symptoms.—It is said, that when they pass the pulse is not quickened, as in inflammation, but on the other hand it frequently becomes slow. I believe that this is generally the case, but the same circumstance will occur in a case of pure spasm. Sometimes, however, the pulse is increased to above a hundred; there is sudden pain in the part, and there is vomiting. Sometimes there is great pain, which is relieved by pressure—it is mere spasmodic pain. Sometimes there is shivering. The patient has no increase of temperature, and the treatment will be the same as that for spasm, because you cannot say whether there is a stone or not; but if the patient have passed gall-stones before, and the same symptoms occur again, then you are authorized in concluding that they arise from gall-stones.

Situations in which they are found.—Now these stones are found in the ducts of the liver itself; they are found in the gall-bladder, in the cystic duct, and in the choledochus. If they exist in the cystic duct, of course they will not produce jaundice except they happen to be so large that they press upon the choledochus, or the hepatic duct; but though they will not produce jaundice, yet they will obstruct the course of the fluid from the gall-bladder, and it will become distended to a great amount by its own secretion. There is a very extraordinary specimen at St. Thomas's, where, from an obstruction in the cystic duct, the bladder went on secreting mucus till at last there was what is called dropsy of the part; but no obstruction of a simple duct can produce jaundice. There must be obstruction in some of the ducts of the liver, in the hepatic duct, or in the choledochus; but they are found in all parts—not only in the cystic duct, but in the gall-bladder itself.

Of all sizes.—Gall stones are seen of all sizes, from mere grit to that of the gall-bladder itself. Gall stones will very often pass without any pain at all, because I have found them in the motions without any pain having occurred. If they are very large they will occasionally produce no pain, provided they lie still and do not attempt to escape; but if nature make an attempt to get rid of them, the pain is very considerable. Dr. Heberden mentions that a stone was found in the gall-bladder of Lord Bute, the preceptor to George the Third, which weighed two drachms, and yet caused no symptoms. They were surprised to find the stone there.

Quantity.—As to quantity, it will vary from one to an immense number. It is

said by Dr. Baillie, that a thousand have been found at once in the gall-bladder, and the preparation is now to be seen in Dr. Hunter's collection. Dr. Baillie has given a representation of the case: an incision is made into the bladder, to shew that it is crammed full of stones. I once took out of the gall-bladder of a patient at St. Thomas's between 300 and 400, which gave rise to no symptoms during life. The patient had not complained of the least pain; nobody knew that there was any thing extraordinary in his inside; and he died of a very different disease. Nothing is more common than to open persons who have died of disease unconnected with the liver, who have never complained of a pain in the side, and yet to find several gall stones.

External aspect.—These biliary stones are sometimes rough, and sometimes smooth. They acquire a smooth surface from lying and rubbing against each other, but then this very same circumstance causes them to be angular; they have a sharp corner and edges, although the surface between the angles may be perfectly smooth. Those in the centre are generally oval; and Dr. Baillie says that he saw one the size of a hen's egg. They will pass through the ducts even when very large, for the ducts will dilate incredibly. We know that the female urethra may be dilated so that a large stone may be extracted from the bladder without an incision. A very large calculus has been known to pass through the ductus communis choledochus, without ulceration having been discovered after death. I mentioned that Dr. Heberden states, that once the ductus communis was distended to an inch in diameter; but not unfrequently when the stones are large they will escape by an abscess, just as pus will do from the liver, either externally or internally. Adhesions will take place externally between the gall-bladder and the parietal peritoneum; an abscess forms, and the stone comes out through the abdominal parietes; but more frequently adhesions take place between the bile passages and the intestines, and they escape that way, so that they are discharged by stool.

Size they may attain, and yet be discharged.—It is astonishing how very large a calculus nature will get rid of, and yet the patient will do well. A calculus two inches and a quarter in length, three and a quarter in circumference, and weighing one ounce, two drachms, twenty-three grains, was discharged from a person, who lived after it and did perfectly well. The case is recorded by Dr. Letsom, in the first volume of the London Medical Memoirs. Dr. Pemberton states that a stone has been discharged two inches and a quarter in

length, and one inch and a quarter in breadth. In the *Medical Gazette* for March 1828, there is an account of one an inch and three quarters in length, three inches and a quarter in breadth, and which weighed 278 grains. A stone measuring an inch and three-eighths in length, and three inches three-eighths in transverse circumference, is mentioned in the twelfth volume of the *Medico-Chirurgical Transactions*; it had passed by ulceration, but the individual died. There is a curious instance of one an inch and six-tenths in length, and an inch and one-tenth in breadth and transverse circumference, which was expelled and the patient recovered; but as it went down, it stuck in the sigmoid flexure of the colon, and there gave all the signs of strangulated hernia. Before its escape from the intestines it did serious mischief; and yet notwithstanding that, there had been no suffering previously; it was not known that the cause of the disease was a stone.

Relative frequency in various parts.—These calculi are most frequently found in the gall-bladder itself; next to that in the cystic duct; next to that in the choledochus; and next to that in the hepatic duct. There can be no doubt, therefore, that they are generally formed in the gall-bladder itself.

Colour.—Some of these calculi are white, others are black; some are black externally and white internally; and some have a shining and semi-transparent fracture.

Constituents.—As to the constituents of these calculi, some of them appear to be nothing more than inspissated bile, and these are bitter to the taste, soluble in water, and burn to a cinder; but the greater part of the biliary calculi are not of this description; they are of an oleaginous character, and if you melt them they will take fire and burn like wax. The shortest way is to scrape them a little, and they very soon melt. Some are resin, some are cholesterine, and some are picromel.

Internal appearance.—Now those kinds which are waxy (I only use the word in the common vulgar acceptance, meaning to burn like wax)—are of a greasy character, are laminated within, and frequently crystallized; sometimes, however, they are oleaginous. Generally they are in plates, laminated, but sometimes there are crystallized radii passing from within outwards. Occasionally they are a mere amorphous mass. Now and then they have been found to contain phosphate of lime; but when stones in these parts contain this material, it is doubtful whether they are biliary concretions. Two cases of this kind are related by Andral, but there

had been such obstruction, that no bile could have entered the gall bladder for some time. The cystic duct was obstructed, and it appears rather to have been a secretion of the inner surface of the gall-bladder, just as stones may be found in the urinary bladder.

DISEASES OF THE GALL-BLADDER.

In regard to diseases of the gall-bladder itself, I may mention that it is rarely ulcerated. Occasionally it is very thick, occasionally it is hypertrophied, and it has been known to be completely ossified. Sometimes it will waste away, sometimes it will have tubercles in it, and sometimes there are hydatids in its substance. Now and then it has been ruptured. A woman came one day to St. Thomas's Hospital, and fell down dead; and on opening her, the gall-bladder was found suddenly to have ruptured. Death took place, I understand, instantly.

ON CERTAIN FORMS

OF

DISEASE OF THE EYE,

Occurring in individuals who were suffering from, or had recently been attacked by, Cholera.

By RICHARD MIDDLEMORE, Esq.

Assistant-Surgeon to the Birmingham Eye Infirmary.

I HAVE recently noticed several forms of disease of the eye consequent on an attack of the cholera, which it is well known was, about a year ago, very prevalent and fatal in various places around Birmingham, and especially at Bilston, Tipton, and Darlaston; and as the circumstance has not been particularly alluded to by those gentlemen who have favoured the profession with their opinions respecting this most destructive epidemic, it has been suggested to me by medical friends to whom I have communicated the circumstance, that it would be desirable to place an epitome of the facts on record.

The forms of disease chiefly presented to my notice as a consequence of cholera, were amaurosis—extensive lymphatic, or puro-lymphatic, deposition between the lamellæ of the cornea—ul-

ceration or sloughing of the cornea—and suppuration of the eye-ball.

In nearly every instance the disease of the eye occurred as the symptoms of the cholera were subsiding; and it was remarked that the appearance of the individuals, even many weeks after the severest symptoms of the epidemic malady had been removed, was extremely unhealthy; their complexion had a yellowish, or dirty white appearance, and they were extremely languid, and much emaciated. I cannot learn that in any instance the ophthalmic affection occurred after saline or other injections into the veins had been practised.

Amaurosis.—The sufferers from this malady had not generally had the cholera very severely, but had sustained an unusual degree of pain in the head during its continuance. Sometimes the amaurosis was complete; in other instances it consisted of slight impairment of vision, very often attended, in the latter case, with either *scotoma*, or what are usually termed *muscæ volitantes*; and in the former instance, with scintillations, or painfully vivid corruscations.

Deposition between the lamellæ of the cornea.—This deposition consisted for the most part of lymph or pus, or of both combined. In some instances it was so abundant in quantity as to induce sloughing of the cornea, or absorption of its lamellæ; and in other instances it was so inconsiderable in amount as to constitute merely a temporary impediment to vision.

Ulceration and sloughing of the cornea.—Sometimes the cornea appeared to ulcerate or slough, without having been preceded by any appreciable amount of inflammation.

Suppuration of the eye-ball.—In every case of suppuration of the eye-ball originating in cholera, which has fallen under my notice, the eye had sustained no inflammation adequate to the production of much pain*; the uneasiness complained of only occurred when the globe became distended, in those instances where the cornea did not ulcerate and slough, and permit the evacua-

* After Magendie has pointed out the occurrence of a suppuration of the eye-ball as a consequence of the division of the fifth pair of nerves, he exclaims, "N'est ce pas un phénomène bien extraordinaire qu'un inflammation vive avec suppuration et insensibilité complète de la partie enflammée, et qui est causée par la section d'un nerf?"—*Journal de Physiologie*.

tion of the fluids contained in the eye-ball.

Remarks on the preceding facts.—I believe it is now admitted by pathologists, that any agent which materially deteriorates the qualities of the blood may give rise to purulent depositions in various parts or organs of the body; and that suppuration of the eye-ball, and ulceration and sloughing of the cornea, are sometimes induced by an extreme diminution of the powers of the system, are events the accuracy of which is equally well established.

Suppuration of the eye-ball, as it is commonly presented to our notice, generally arises from ophthalmitis, whether idiopathic or traumatic; and from gonorrhœal or purulent ophthalmia, or some equally severe form of inflammation of the eye; but the experiments of Magendie (*Journal de Physiologie*, tom. iv. p. 176—302) prove that it may also arise from injury to certain nerves, of which, until the publication of his experiments, we had scarcely any knowledge. He divided the fifth pair of nerves in the temporal fossa, and he found that the cornea became slightly opaque twenty-four hours afterwards, and that, five or six days after the division of the nerve, it was “*de la blancheur de l'albâtre*.” Towards the eighth day, the cornea was separated in part from its connexion with the sclerótica, and finally so extensively ulcerated as to permit the discharge of the humours of the eye, which were thick and partly opaque: the eye-ball then collapsed. In fact, subsequent experiments proved that suppuration of the eye-ball generally follows the section of the fifth pair of nerves, on the side upon which such section has been made; and we have accumulated a mass of cases which determine, beyond dispute, that injury or disease of the fifth pair of nerves are among the causes of suppuration of the eye-ball*.

Suppuration of the globe has sometimes followed the ligature of the carotid artery, and the same occurrence has

taken place after the performance of other severe operations; just in the same way, I apprehend, in this latter instance, as purulent deposits are apt to occur in various parts of the body, after any important and severe surgical operation, whatever may be its nature. Let me be understood to say, that suppuration of the eye-ball may take place after the performance of any severe surgical operation, on the same principle, and from the same causes, as those which originate purulent deposits in other parts or organs of the body after the accomplishment of similar operations; and let me also be understood to make a decided distinction between the occurrence of suppuration of the eye-ball after the ligature of the carotid or the section of the fifth pair of nerves, and the existence of purulent effusion within the globe, after, for example, the amputation of a limb; or, indeed, from any cause suddenly and materially vitiating the quality of the blood. The term “suppuration of the eye-ball” would be applicable in both instances; but the mode in which these two sets of causes operate in producing such suppuration, appears to be quite distinct. On the subject of purulent depositions after severe injuries or important operations, much interesting information may be found in the surgical works of Baron Larrey, Desault, and Guthrie, and also in an excellent paper in the fourteenth volume of the *Medico-Chirurgical Transactions*, by the late Mr. Rose, and in the fifteenth volume of the same work, by Mr. Arnott. Mr. Wood, the distinguished senior surgeon of the Birmingham Hospital, tied the common carotid artery of a man (Joseph Lycett) who had produced aneurism of that vessel by an attempt to commit suicide with a pen-knife, and in the course of a short time suppuration of the eye-ball took place; and in this case, post-mortem examination detected many abscesses, both in the cortical and medullary part of the brain. A similar result occurred in the practice of Mr. Wardrop. I have not noticed this occurrence after tying the internal jugular veins, which I have accomplished twice in dogs; but the face and parts beneath the jaws are rendered excessively cedematous when both the internal jugular veins are tied at the same time: but of course suppuration of the eye-ball would be the more likely to occur in

* In a case of phlebitis which occurred in the practice of Mr. Earle, in which suppuration of the eye-ball took place, the fifth pair of nerves was found to be very soft and much flattened; so that it is doubtful if the diseased state of the nerves did not itself induce the affection of the eye. This circumstance does not appear to have occurred to the memory of Mr. Arnott, who attributes the disease of the eye to the inflammation and suppuration of the vein.

proportion as the phlebitis is severe, and its effects determined by various causes to that particular situation.

Inflammation of the veins is sometimes succeeded by suppuration of the eye-ball, in whatever part of the body the phlebitis may occur; but as the uterine, the femoral, and the iliac veins, are more generally the seat of inflammation in connexion with parturition, suppuration of the globe is consequently more frequently referrible to their inflammation than to that of the veins in other situations.

CHEMICAL ANALYSIS OF THE SERUM OF THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

WE shall be obliged by your inserting in the columns of your journal the following remarks on the serum of the blood.—We are, sir,

Your obedient servants,

R. H. BRETT.
GOLDING BIRD.

Guy's Hospital, June 25, 1833.

Having performed some experiments a short time since on some serum obtained from the blood of a patient labouring under diabetes, with a view to determine if possible the presence of urea in that fluid, the only indication we obtained of the existence of that substance was what we imagined at the time sufficiently determinate, viz. the strong urinous odour evolved, when the alcoholic extract, obtained by a process shortly after to be described, was treated with diluted nitric acid, and the excess of the latter removed by heat. Suspecting, however, that healthy serum, or at least serum obtained from persons neither labouring under diabetes, or anasarca with coagulable urine, might probably afford the same results, we undertook a careful examination of that fluid, repeating it several times on different portions of serum, procured from persons whose urine was totally free from any albuminous impregnation, and who were suffering only from trifling ailments. The following were the results obtained:—

When the serum of blood is coagulated and kept at a temperature of 224°

F. in a salt-water bath for some time, a perfectly dry horny mass remains, not undergoing the slightest fusion, or becoming deliquescent or moist by exposure to air, even after some days. If this mass be digested in boiling water, or alcohol, for some time, and the fluid then filtered and evaporated to dryness in a salt-water bath, a semi-transparent substance is obtained, mixed with cubical crystals of common salt. If this substance be subjected to a temperature insufficient to char it, a peculiar odour is evolved, very similar to that observed during the panary fermentation, but it does not, however, become soft, or give the slightest indication of fusion. When treated with diluted nitric acid a slight degree of effervescence takes place; and when the excess of acid is removed by the application of heat, the crystals are found to possess a nitrous taste, from the partial decomposition of the chloride of sodium, and the consequent formation of a nitrate of soda, whilst a strong urinous odour is evolved from the animal matter.

Incipient decomposition does not prevent the peculiar action of nitric acid on the extractiform mass. Thus when the fluid obtained by treating the dried albumen with boiling distilled water was kept for nine or ten days, in a vessel half-full of atmospheric air, it became very turbid, a strong smell of sulphuretted hydrogen was evolved, and the sides of the glass were blackened by the reaction of the gas on the lead contained in it. When this fluid was evaporated to dryness, and treated in the manner before described, exactly the same phenomena occurred. When the extractiform mass obtained from the aqueous solution was heated in a platinum capsule to redness, it did not fuse, swell up, or leave a very bulky charcoal; the odour of burnt bread was given off. When heated in a glass tube closed at one end, no sublimate of carbonate of ammonia was formed.

Neither ammonia, the muriatic or sulphuric acids, are capable of evolving a urinous odour when boiled with this substance.

Chlorine, when passed through an aqueous solution of this extract, caused a manifest turbidity; but no urinous odour could be perceived by subsequent evaporation.

When the extractiform mass, previously treated with nitric acid, and the

excess of acid removed by evaporation, was exposed to a temperature of about 250° , it underwent no fusion; and when heated with caustic potass, evolved no ammoniacal odour.

When the alcoholic solution of this peculiar substance was allowed to evaporate spontaneously, no prismatic crystals were obtained, but a few cubical crystals of common salt.

When a portion of the same solution was evaporated to one-fifth, and treated with nitric acid, not the slightest trace of crystalline plates could be perceived, even after some time had been allowed for spontaneous evaporation, but a gradually increasing urinous odour was evolved.

The following quantitative analysis of a fresh portion of serum was then instituted:—

100 grs. of clear serum, specific gravity 1·028, were evaporated to dryness over a salt-water bath, at a temperature of about 224° F. The horny brittle mass thus obtained was found to weigh 10·16 grs.; deducting this from the previous 100 grs. of serum, left 88·63 grs. as the weight of water. The dry albuminous mass was then reduced to powder, and digested in boiling water for twenty minutes; the whole was then thrown upon a filter, and the latter well washed with boiling distilled water, until the fluid which passed through no longer affected nitrate of silver. The solution thus obtained was nearly clear, and perfectly colourless. When evaporated to dryness in a salt-water bath, the residue weighed 1·21 gr. consisting of the peculiar animal matter, with chloride of sodium and lactate of soda. The whole of this residue was ignited in a platinum capsule, over a spirit-lamp with a circular wick, and the heat urged to bright redness. By this means all the animal matter was driven off, and a perfectly white ash remained, weighing ·73 gr., which being deducted from the weight of the residue obtained by the last evaporation, left ·48 gr. as the weight of the animal matter, together with a portion of lactic acid, which must have been decomposed at the temperature. The saline residue exerted a slight alkaline reaction, and effervesced when treated with a small quantity of acetic acid. By evaporation the excess of acid was driven off, and the heat raised so as to decompose the latter and leave a perfectly

white ash; this last, treated with boiling alcohol, specific gravity 833, until the last drops which passed through the filter no longer affected nitrate of silver, upon evaporation cubical crystals were obtained; these, after exposure to a red heat, weighed ·62 gr., consisting of chloride of sodium, leaving of course ·11 gr. for the weight of the carbonate of soda resulting from the decomposition of the lactate.

From this analysis we have concluded that the following are the proportions of the constituents of 100 grains of serum:—

	Grs.
Water.....	88·63
Albumen.....	10·16
Peculiar animal matter, with a portion of lactic acid....	} ·48
Chloride of sodium.....	
Carbonate of soda resulting from the decomposition of the lactate.....	} ·11
	100·00

That this peculiar animal matter may be, and probably has been, mistaken for urea, can hardly be doubted, especially since a urinous odour has by many been considered as indicative of the existence of the latter. We have therefore thought it well to point out in what manner they differ from each other, and that the urinous odour is no proof at all of the presence of urea, nor does it essentially belong to that principle. In the first place, a diluted aqueous solution of urea undergoes decomposition by prolonged ebullition, as does it also when kept for any time, more especially when mixed with extraneous matters. The peculiar substance in question, on the contrary, may be kept at a temperature of 224° for twenty minutes, or even longer, without losing its properties; and when kept exposed to the air so long as to cause the evolution of sulphuretted hydrogen, it still evolves a urinous odour when treated with nitric acid. Urea, when allowed to crystallize from its alcoholic solution, yields distinct prisms; and so small a quantity as $\frac{1}{30}$ gr. of this principle yields a distinct crystalline scale with nitric acid. No such effect is produced by treating the substance in question in a similar manner: urea fuses at a temperature of 248° , whereas this peculiar animal matter gives no indication of fusion at any temperature; but above

all, neither urea or the nitrate possess any urinous smell when pure, as the following experiments will sufficiently prove. Some urea was obtained by the common process of heating the extract of urine with alcohol, and freeing the alcoholic solution as much as possible from colour, by means of animal charcoal. The crystals obtained by evaporation still had a yellow tinge; they were accordingly digested in different portions of sulphuric ether, until every trace of colour was removed. The urea thus obtained was dissolved in alcohol, and by evaporation perfectly colourless and inodorous prismatic crystals were procured: when some of these were dissolved in a small quantity of water, and nitric acid added, crystalline plates began to form in abundance, and when the excess of nitric acid was removed by careful pressure between folds of blotting paper, they were found to be quite colourless, and free from odour. When, however, the ethereal solution was evaporated to dryness, and treated with nitric acid, a powerful odour of urine was instantly given out.

When artificial urea, obtained by decomposing cyanite of lead by caustic ammonia, filtration, and evaporation, was treated with nitric acid, colourless crystalline plates were obtained totally free from any urinous odour.

We regret that we have not been enabled to subjoin an analysis of the serum from the blood of a patient labouring under anasarca, with coagulable urine, in which form of disease urea is said to exist very abundantly in the serum; we shall, however, take the earliest opportunity of transmitting to you the result of our experiments on that point.

ARTIFICIAL ANUS FROM SLOUGHING—

SUCCESSFULLY TREATED.

To the Editor of the Medical Gazette.

SIR,

I HAVE enclosed the particulars of a case of artificial anus, the result of mortification of intestine in a strangulated hernia. Should you consider the case

of sufficient interest, you will oblige me by inserting it in your Gazette.

I am, sir,

Your obedient servant,
ROBERT BENINGTON.

6, Queen-square, Aldersgate-street,
June 8, 1833.

George Jones, æt. 35, who had for several years been the subject of femoral rupture, on the morning of August 10th went to his employment without putting on his truss. Whilst making some unusual exertion the hernia suddenly came down, larger in size than it had hitherto appeared; its descent being followed by vomiting, severe pain in the abdomen, and in the hernial swelling. Having failed in reducing the hernia by the means he had usually resorted to, he returned to his home, and applied for assistance to a practitioner in his neighbourhood. The symptoms continued with great severity during that and the two following days, no other measures being had recourse to for his relief than the frequent administration of purgative medicine and enemata; but the former was rejected by the stomach as soon as swallowed, and the latter returned without procuring any evacuations. On the evening of the third day from the accession of the symptoms, he experienced a sensation as though something had burst within the tumor, which, however, did not become altered in size; almost immediately after this the pain in the belly subsided, the retching ceased, and copious evacuations from the bowels took place. Two days afterwards I was requested to visit him; there was then, in the upper and inner part of the right thigh, a large fluctuating swelling, the integument covering it being inflamed, and having a slough the size of a crown-piece, occupying the centre. On dividing the slough, about half a pint of dark-coloured matter, having a fetid odour, escaped. The man being then quite free from pain or tenderness in the abdomen, and without any particular disturbance of bodily health, was merely desired to remain in bed, and to have poultices applied to the wound. The discharge of fetid puriform matter continued during three or four days, until the separation of the slough, when a tolerably healthy looking surface was exposed. A quantity of faecal matter now passed through the wound, making

it necessary to change the poultices rather frequently; stools, however, were freely voided by the natural passage. He was directed to retain the recumbent posture, to keep the bowels open with castor oil, and to restrict himself to the use of a light farinaceous diet. At the expiration of a month the wound was nearly filled up by granulations, and the quantity of fæces escaping through it considerably diminished. A compress of lint was now lightly confined over the opening by adhesive strapping; but this required to be removed several times in the day, to permit the discharge of fæcal matter. The pressure was gradually increased, and the wound lessened in size, until in about three months a mere pin-hole aperture remained, through which a slight quantity of fæces was occasionally discharged; but in two or three weeks this closed, and a sound cicatrix remained.

This was doubtless a case of neglected strangulated hernia, followed by mortification of the intestine, and effusion of its contents into the sac, giving rise to inflammation and sloughing of the integuments. The occurrence of the hernia on the right side, and the nature of the discharge from the artificial opening, render it probable that the cæcum, or the first portion of the colon, formed a part of the contents of the hernial sac. As free passage of the fæces by the rectum was established directly after the cessation of the symptoms of strangulation, and continued through the entire period of recovery, it is probable that a portion only of the circumference of the gut was included within the stricture, or that a portion of the mortification was confined within a very circumscribed limit, so that the intestine, on the separation of the slough, and consequent diminution of its bulk, receded within the abdomen, leaving the aperture at the mouth of the sac. In either case no material interruption of the continuity of the canal would be occasioned; and the artificial anus would readily admit of cure by natural processes.

In cases of artificial anus, it not unusually happens, that after the natural course of the fæces through the intestines has been restored, the external opening closes, with the exception of a slight fistulous aperture, which occasionally permits the escape of a little fæcal matter, and resists all attempts to

heal it. Various means have been resorted to for closing the opening in these cases, such as paring off the edges of the wound, touching them with lunar caustic, &c. Steady employment of the graduated compress, and the spica bandage, together with preventing any obstruction in the intestinal canal, by keeping up regular alvine evacuations, and confining the patient to light and easily digested food, seem to offer the most probable means of obtaining a cure.

CROTON OIL AS A COUNTER-IRRITANT.

To the Editor of the Medical Gazette.

SIR,

I HAVE, for a considerable length of time, been in the habit of using croton oil, in its concentrated state, by means of friction, to the chest, in phthisical cases; and have found, in many instances, the greatest possible advantage from its application.

I generally direct it to be rubbed on the sternum, or on the part indicated by pain or uneasiness; and, by repeated applications, keep a fresh crop of vesicular eruption continually rising: two or three drops, night and morning, will mostly be found sufficient for this purpose. It is necessary to caution the person applying the oil, not to look at it during the time it is rubbed, in order to prevent a very troublesome swelling of the palpebræ following its use.

If you think this hint worth communicating in the Gazette, it is very much at your service.

I am, sir,

Your very obedient servant,

R. HOBSON, M.D. Cantab.

Leeds, June 24, 1833.

ANSWERS TO THE QUESTIONS OF PHILALETHES,

RESPECTING DR. W. PHILIP'S OPINIONS.

To the Editor of the Medical Gazette.

July 8, 1833.

SIR,

In the last number of the Medical Gazette, Philalethes supposes that he has

pointed out an inconsistency in Dr. Philip's Inquiry into the Laws of the Vital Functions, and puts two questions to him. He is not aware that the power of volition remains after the brain and cerebellum are removed, if the medulla oblongata be left undisturbed; and that Dr. Philip, so far from regarding the eighth pair of nerves as the only channel through which nervous influence is conveyed to the lungs, has shewn, by several experiments, that the effect on the lungs of destroying a certain portion of the spinal marrow, is the same as that of dividing the eighth pair of nerves. The influence which passes by both channels, as far as the brain and cerebellum are concerned, is conveyed through the medulla oblongata; and, consequently, when this part is destroyed, both are obstructed.

This writer also forgets that, in the experiments he refers to, the eighth pair of nerves forms communications with various nerves above the part at which it was divided.

I am, sir,
Your obedient servant,
CRITICUS.

ON THE NECESSITY
OF A
PARLIAMENTARY INQUIRY INTO
THE PRESENT STATE OF THE
MEDICAL PROFESSION.

To the Editor of the Medical Gazette.

SIR,

THAT a movement now exists for effecting a change in our medical institutions, is obvious to every one; and I trust that an impartial and honourable inquiry may be ere long instituted, and that the general discontent may be thereby terminated. We have an old proverb—"a disease known is half cured." Comparison alone is the logical method of distinguishing right from wrong. As followers of a profession whose unequivocal utility is universally admitted, we ought to employ our utmost and never-tiring endeavours to place its foundations on real science and practical knowledge. The sacred name of science should not be prostituted to lower and mercenary purposes.

The questions at issue among us are these:—Are the medical institutions of these kingdoms sound, rational, and adapted to the present condition of a country which nobly stands in the front rank of the great moral contest which is now fighting for the rights of civilization and humanity throughout the world? Can the most bigotted conservatist of error and abuse deny the existence of anomalies in our institutions, which retard the free, equal, and advantageous exercise of our profession by the respective subjects of our most gracious monarch? Do the Colleges of Physicians and Surgeons of London, Edinburgh, and Dublin, the Faculty of Physicians and Surgeons of Glasgow, and the Companies of Apothecaries of London and Dublin, possess the power of procuring for the persons admitted to their respective degrees, diplomas, licenses, and certificates, an equal quantum of honourable esteem? Are the members of the aristocracy and commonalty of England, Ireland, and Scotland, liable to diseases and casualties of such essential difference in their nature, as to require a maximum of medical skill in one locality, and a minimum in another? The voice of truth replies in the negative to each of these inquiries.

I will now, Mr. Editor, submit to your impartiality another important question. Is not the literary, scientific, and professional education of the doctors of medicine and surgery in Germany and France, especially those who have graduated at Berlin, Goettingen, Leipzig, Heidelberg, and Paris, secured by a system of education immeasurably superior to that which is generally prevalent in this country? The "officiers de santé" of France, or the practitioners of "bassa chirurgia" in Italy, a class of half-educated men, resembling the Potions and Crabs of our humorous brother Tobias Smollett, we would wish to consign to oblivion, since they tend to vitiate the general excellence of the institutions of those countries. To my last query, every liberal man who has had opportunities of personal observation, must reply in the affirmative. Perhaps you may maintain, that with all their splendid opportunities, and indefatigable ardour in pathological research, the average ratio of mortality in medical practice is much higher on the continent than in this country. Be it so: an easy solution is at hand. The

strong sense and sound judgment which distinguishes our countrymen in general, prevents their medical brethren from encountering shipwreck amidst the mazes and quicksands of ultra-speculative theory. The monomanias of Broussais and Hahnemann will take no deep root on British soil, whilst we can appreciate the value of "*sangues à l'épigastre*," and the danger of being ultra-Hamiltonians, on the one hand, in very many cases of disease, without running into the opposite extreme of allowing our patients to make their exit through the passive ordeal of a "*potion gommeuse*," or a "*lavement emollient*." We never boast of our rank as an inventive nation, though we possess the acknowledged power of separating the wheat from the chaff, and profiting by the experiments and discoveries of others. Though our country was not the birth-place of Gioja or Galileo, we may fairly pride ourselves in our improvements in nautical and astronomical science, under the accomplished and experienced hands of a Parry and a Herschel. A few years since our youth were obliged to repair to Edinburgh for competent clinical education, no equal degree of information being to be had at any of our other medical schools; this, though the best at the time, was acknowledged to require such amendment, when compared with the clinics and polyclinics, both medical and surgical, of Germany, as to call from the pens of those able and accomplished practitioners, Dr. John Thomson and Dr. James Clark, recommendatory admonitions for the consideration of the Northern Royal Commission. Whether their judicious advice has been acted upon, I know not. The following are the chief anomalies of which the profession at large have most reason to complain:—The imposition of religious tests at the English Universities; the neglect (till of late) of enforcing adequate classical attainments at Edinburgh; the exclusion of the membership of the Dublin College of Surgeons to all save their own apprentices; the Faculty of Physicians and Surgeons at Glasgow establishing a complete monopoly of their own populous district; the London and Dublin Companies of Apothecaries each requiring a different extent of qualification for their licenses; and, to crown all, the ineligibility of any graduated physician to take care of the lives of his Majesty's

subjects in a metropolis containing a million and a half souls, though he is permitted to employ his ignorance to the disadvantage of the worthy inhabitants of Manchester, Birmingham, Liverpool, Bristol, and other large towns, whose population places them upon a par, in a politico-economical point of view, with half the capitals of continental Europe.

The time for the removal of these anomalies must soon be at hand. The powers of the public mind are now developed beyond all former precedent, and the dread and apprehension of innovation will soon degenerate into a mere "*brutum fulmen*." Should the worthy lawyers of the age of Cromwell return to earth, and proclaim upon their writs that the end of the world was at hand, or another honest Sir Robert Filmer send forth from the press the "*Anarchy of a limited and mixed Monarchy*," their appeals to the belief and confidence of mankind would pass unheeded; the falsehood of their conclusions being recognized by the tangible existence of opposite and practical proofs. The progress of sound and rational medical reform, as our friend Blackwood would call it, will be cleared of every obstacle by the lever of a thorough parliamentary investigation. Our legislative assemblies, in future, will not permit the despotic agents of Frederick William, the constitutional advisers of Louis Philippe, or the republican government of North America, to secure for Prussia, France, or the United States, the advantages of more scientific, liberal, and practical medical institutions than the great and glorious country of Great Britain can yet boast of.

The important change which I advocate will probably be accelerated by the present discussions on the Apothecaries' Amendment Bill. To the Apothecaries' Company much praise is due for improving the general stand of medical knowledge: this must be admitted even by those who think with you (*Med. Gaz.* June 29th ult.) that they ought not to have been made the depositaries of so much power as that of dictating the standard of medical acquirements to the profession at large, and of controlling and putting down quackery and illegal practice. This power should have been delegated to, and exercised by, the higher medical authority of the Colleges of Physicians and Surgeons.

In an outline of an improved system

of medical education, the chief desiderata would be,

1st. The universality of adequate classical and scientific attainments, preliminary to a course of medical study.

2dly. Uniformity of medical education in England, Scotland, and Ireland.

3dly. The non-division of the study of the three branches of the profession, and the proper or optional division of their practice.

These leading objects may be thus attainable:—Let the whole of our medical corporations be condensed into three Universities or Faculties of Medicine, at London, Edinburgh, and Dublin; each possessed of equal powers in conferring degrees upon all who are qualified, and likewise of ample authority of suppressing quackery and controlling unlicensed practitioners in their respective districts. Let two years subsequent to the routine of general school education be devoted to the study of the principles of natural and moral philosophy, besides making further progress in the classics and the modern languages. This time can with advantage be deducted from the years of apprenticeship; which may be limited to one, for the purpose of acquiring a due knowledge of pharmaceutical manipulation and the general principles of the science. This biennial period of preliminary study would enable the student to pass such an examination as to entitle him to the degree of Bachelor of Arts or Sciences. The possession of this degree should be a *sine quâ non* previous to being entered as a student of medicine. Let four years be spent, at one more of the three universities, in the study of every branch of medical science; each year to consist of a winter and summer session of five months each. Let regular annual examinations take place, to ascertain the relative annual progress of each pupil. At the end of four years, let the candidate be examined in anatomy on the dead body, or anatomical preparations; in chemistry and pharmacy in the laboratory; in surgery, in practical operations; in medicine and midwifery, in the clinical wards of an hospital. After this ordeal, let the candidate be at liberty to take the degree of Doctor Medicine or Doctor Chirurgiae, or both, according to his individual option. Let this examination be final, and the degree be equivalent to an "ad eundem" at the other Universities. Another improve-

ment of the highest national importance might be suggested in the institution of a College of Pharmacy, in conjunction with each of the established medical faculties. Such encouragement to chemical talent would soon furnish us with Robiquets, Pelletiers, Caventons, and Vauquelins, and we should compete with our neighbours in the discovery of new active principles in the *materia medica*, though they forestalled us in quinine, strychnine, and a whole host of others. Let the Colleges of Pharmacy be required to examine all those who profess to dispense medicine, whether practitioners or druggists, and to institute penal enactments against every individual who ventures to practise pharmacy without the qualification of their license.

The above views and opinions are derived from reflection and a fair share of personal observation; and whether or not they are considered applicable to the wants of our common country, in the present state of medico-political agitation, I leave it to the candour and judgment of your readers to decide.

Your obedient servant,

WM. ENGLAND, M.D.

Norwich, July 4, 1833.

SMILAX ASPERA AN ANCIENT REMEDY.

To the Editor of the Medical Gazette.

SIR,

Of the numerous valuable uses of your publication, not the least is the opportunity it affords of drawing the attention of medical men to the virtues of medicines not in common use, but whose efficiency in the cure of diseases is well worthy of their regard.

In your thirty-seventh number I perceive an account of the *smilax aspera*, which appears to be equally, if not more serviceable, than the costly sarsaparilla; and, in corroboration of the statement of its merits, I have to observe that it has obtained a place in the *materia medica* of Dioscorides, and perhaps it was, from his recommendation chiefly, introduced into European practice in 1535, at which time the study of classical medicine extensively prevailed.

A reflection of a late very eminent scholar (Dr. Parr) has given rise to a

series of publications, which, in all probability, will diffuse a classical taste throughout the country, and which ultimately may produce the greatest benefits to the community at large; and I should be glad to hint, through your publication, that a similar series of the medical works of the ancients would prove of the highest utility to medical science;—I mean a translation, as literal as possible, with an appendix of notes and indexes, of the Greek, Roman, and Arabian physicians.

I am, sir,
Your obedient servant,
J. COVE, M.D.

Coventry, June 24, 1833.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégér.”—D'ALEMBERT.

Observations on the Testicles. By JAMES RUSSELL, F.R.C.S. late Regius Professor of Clinical Surgery in the University of Edinburgh, &c. &c.

THIS little book is full of excellent matter, and is a model of conciseness. The author gives in it the substance of the lectures which he delivered on the Testicle many years ago, matured of course, and much improved, by subsequent experience and study. He does not fill the book with cases, which, indeed, he seems rather systematically to avoid; but prefers in general a single case, well chosen, which he deems “often sufficient to establish an important point in the most satisfactory manner.”

Concerning the *number* of testicles the author mentions some curious facts. A few cases of monorchides are found in the records of medicine; but they seem to be equivocal, as they are generally no more than a coalescence of the two testicles, and the single body thus formed is attended by two spermatic cords, running either to the same or different sides of the abdomen. With regard to supernumerary testicles, it is known that neither Morgagni, Haller, nor Meckel, ever discovered a third testicle in their dissections of reputed triorchides, and that they accordingly doubted the existence of such a condition.

“But their scepticism does not seem to me to be well founded, since there is

nothing in the structure of the testicles, or in their connexion with other organs, to render their multiplicity incompatible with the arrangement of the animal economy: and no person, however well informed, is entitled to discredit the possibility of an unusual appearance, merely because it has not fallen within the sphere of his own observation. Leal Lealis, an author of high respectability, discovered a third testicle in the body of a man whom he dissected. This discovery sets the question at rest, by establishing the existence of a genuine triorchis; and the certainty of the fact being once established, renders the accuracy of the cases reported by different authors much more probable. A prominent and well marked case of this kind is reported by Mr. Blumener, of a person with three testicles in the scrotum, two in the left side, one lower, the other higher, nearer to the aperture of the inguinal canal, provided with its full grown epididymis and spermatic chord, and which could not be mistaken for any preternatural growth, as it had the shape, firmness, and sensation of the other testicle. The sensation communicated by pressing a testicle is peculiar and characteristic.”

Some apocryphal cases are on record of persons having four, five, and even six testicles. In the latter case four were said to be of the natural size, and the other two much smaller. The stories which are current about the excessive propensities of persons so formed need scarcely be alluded to. The case of the Landgrave of Hesse, who figures in Luther's life by Bayle, is pretty generally known. Mr. Russell mentions that a dog, remarkable for his sagacity, had two testicles in the scrotum and one in the abdomen.

In his remarks on the descent and development of the testicles, the author well describes the peculiarities attending the period of puberty, and points out the injurious consequences of too early and excessive indulgence of the venereal appetite.

“M. Volney, in his *Travels through Asia Minor*, mentions that the people of rank in that country, who can afford the expense of keeping seraglios, are, in general, impotent at the early age of thirty. Matters are not so bad in this country, though it is a well known fact, that young men of fashion, who indulge their amorous propensities to excess at an early age, lose the power of

procreating sooner than the more continent, and are familiarly distinguished by the quaint appellation of God's Geldings. I never have been able to discover any exterior marks of discrimination, to distinguish these from other men: but the ladies, who are more discerning in such matters, predicted, in a district of country with which I am acquainted, of six gentlemen in the prime of life, that they never would beget children. The event verified the prediction, as all the six were married, and every marriage proved barren. The defect rarely goes farther in this country than to prevent individuals from procreating heirs to their estates. I have known very few instances of more calamitous consequences. In one distressing case, of a young gentleman of rank and fortune, the effect of premature and excessive indulgencies weakened him so much, that he lost all enjoyment of life, sunk under a degree of despondency which did not admit of consolation, and, though I encouraged him to marry, in full confidence of his recovering his health by prudent management of his constitution, he would not listen to my exhortations, and drowned himself in a fit of despair. From the general tenor of the above statements, and particularly from the melancholy catastrophe of the last case, every one concerned in the education of youth must perceive the importance of preventing the minds of young men from being corrupted by impure addresses to their imaginations during the early years of their lives."

Some most judicious observations are added respecting the treatment of persons morbidly irritable.

Of the diseases of the scrotum we have here also an excellent summary. We shall extract what the author says of tumors:—

"The most singular disease of the scrotum is the growth of a tumor of enormous size. In a memorable case of the kind, *Ger. Ephr.* 1692, the tumor attained the weight of more than 200 pounds, a weight considerably greater than the weight of a well-grown man of ordinary stature. These tumors, in general, begin insensibly without pain, and are not perceived till they attract notice by an obvious swelling. In a few cases they are the consequences of a blow, or their commencement is marked by a slight attack of pain, which is temporary, and does not return during

the course of the complaint. Their progress is gradual and regular, and they may often be traced back for fifteen or twenty years. They do not occasion any inconvenience, excepting what arises from their bulk and weight. They are not only free from pain, but endued with very low powers of sensibility, since neither the application of caustic, nor the introduction of setons, excite any troublesome degree of irritation. A friend of mine, who practised some time in the West Indies, informed me that the rats sometimes fed upon these enormous tumors, while the patient lay in a most helpless condition, and was unable to defend himself from their attacks. The tumors bore being handled with considerable roughness, without the patient suffering from this rude treatment, excepting when the pressure was made on the part of the surface corresponding to the situation of the testicle; then, indeed, the patient complained of pain, as the testicle still retained its natural sensibility, or even possessed it in an unusual degree. The growth of such immense swellings does not affect the constitution, nor produce any symptom of debility. It does not, in all cases, even impair the function of generation, as *Delpech* particularly mentions that neither the penis nor testicles had lost any thing of their natural faculties. . . .

"This very singular disease of the scrotum belongs to the warmer climates of the globe, the East and West Indies, and the correspondent latitudes of Africa. It is endemic, and very prevalent among the Bambara nation, on the coast of Guinea, among whom the misfortune of having a monstrous testicle is regarded as a mark of nobility. When the patient goes out to ride, the testicle is supported on a bowl placed on the pommel of the saddle; and when of the largest size, supported on a sheet passed over the shoulders, and dragged along the ground when he attempts to walk. I know of only two well-authenticated cases of this disease having originated in Europe. One occurred in the practice of *Mr. Liston*, surgeon to the Royal Infirmary, Edinburgh; and the other in that of *M. Delpech*, of Montpellier. There is a third case by *Mr. Hall*, of Manchester, probably of the same kind, though, as the symptoms are not decidedly marked, I have not included it in the number of well-authenticated cases. In the West Indies, the disease was long confined to

the Island of Barbadoes. But of late years it has spread extensively over many of the other islands, from causes wholly unknown, and is now a disease of very frequent occurrence."

With regard to the treatment by excision, Mr. Russell thinks that "on taking a general survey of all the cases of enormous tumors of the scrotum which have been operated on, there is great encouragement to undertake the operation." Success is generally the result, and failure, when it has occurred, has been usually owing to special circumstances. The desire of saving the testicles is what mostly tends to render the operation critical. Mr. Liston, in attempting to operate with this view, was forced to abandon it in consequence of the quantity of blood lost on the first incision; he had to proceed with all possible dispatch to finish the operation, which he did in not very many seconds. Yet, notwithstanding this celerity, the patient's strength was so much exhausted by the hæmorrhage that he fainted, and did not revive till by repeated doses he had, at short intervals, taken a pint of strong whiskey. In another case, where the operation was performed by Mr. Wilkes, the patient died on the table, after he had been under the hands of the surgeons for nearly eight hours. There are in all thirteen or fourteen cases of operation on record, and there is no instance of a recurrence of the disease in another part of the body.

Affections of the tunica vaginalis next come under review; and the subject is summed up with Mr. Vaughan's case, in which the patient died of what was supposed to be inflamed testicle. The tunica vaginalis was found to be two-thirds of an inch in thickness, with the testicle and epididymis lying in the vaginal cavity, not at all enlarged, and healthy in every respect.

"This memorable case exposed the imperfection of surgery with regard to the diagnosis of inflamed testicle, without pointing out any discriminating symptom which would prevent the recurrence of a similar mistake. Fortunately, indeed, our imperfect knowledge on this point does not lead to improper treatment, since, in the early stage of all cases, the indications of cure are the same; and even in the latter stage, when the case becomes critical, it is safe to make a deep incision into the substance of the swelling."

Hydrocele is very compendiously treated by our author. In noticing the diagnosis of this complaint he says—

"A hydrocele may be mistaken for a disease of a very different nature, or, conversely, another disease mistaken for a hydrocele; or, although the case be actually a hydrocele, it may be accompanied with singular circumstances, which are not disclosed at the time of the investigation. Thus a hydrocele retaining its transparency may, instead of containing a fluid, contain a collection of hydatids. This case, though rare, I have known to occur, to the great embarrassment of the operator. A still more rare instance of a case of transparency not being an absolute criterion of hydrocele, is mentioned by Richter, in the case of a patient who had a rheumatic swelling of the testicles, in which the affected testicle was transparent. The affection passed from the one testicle to the other, an alternation characteristic of rheumatic complaints. Besides hydatids, I have known an adventitious encysted transparent tumor adhering to the epididymis, and filling part of the tunica vaginalis. The existence of such a tumor is not known previously to the operation."

The form of a hydrocele is by no means invariable. Although the long axis is commonly vertical in the erect position of the patient, yet Mr. R. has known it horizontal, the apices projecting anteriorly and posteriorly; and sometimes it acquires an hour-glass form. As to the bulk which a hydrocele may attain, after mentioning the case of Gibbon, from whom six quarts of fluid were drawn, our author quotes Mursinna, who gives an account of one, perhaps the largest on record—the long axis being twenty-seven inches, the transverse seventeen. Of the two principal methods of treating hydrocele, namely, by injection and by incision, our author gives the preference to the latter. That we may not mis-state him on this point, we give his words:—

"The cure by incision, when properly conducted, accomplishes the complete obliteration of the vaginal cavity, which renders a relapse impossible. A gentleman who had the cure by injection performed without success, submitted afterwards to the cure by incision, and declared that the cure by injection was the more painful of the two. I have

paid great attention to the subject, with the result of finding my confidence in the certainty and permanence of the cure by injection gradually abate. The confidence of the London surgeons, too, so far as I can learn, is likewise on the decline; and on the Continent, the cure by incision is, I understand, generally employed."

The two remaining divisions of the volume are on the diseases of the testicles, and the diseases of the spermatic cord. The first occupies a space proportioned to its importance, and deserves the perusal of every surgeon. Many of the observations in this part are original, and most of them curious. We extract what is said about *gout* in the testicle.

"The testicle is likewise liable to be affected by *gout* very much in the way it is affected by *rheumatism*. From a characteristic difference, however, between the two diseases, the origin of the attack is often more completely concealed, so that nothing appears to excite suspicion till the supervention of *gout* in other parts of the body relieves the testicles, and develops the mysterious nature of the case. In some cases of this kind, the attack has commenced with a sudden swelling of the testicle, which was remarkable for its extreme hardness and weight. These symptoms being by some surgeons regarded as pathognomonic of a cancerous scirrhus, have led to the unfortunate practice of removing the testicle by castration. I have seldom in the course of my own experience had occasion to witness an attack of *gout* in the testicle, but the attacks which I have witnessed were marked with the impenetrable hardness, and increase of weight, so characteristic of the complaint. A *gouty* affection of the testicle is rather a rare occurrence, so that there is not any appropriate treatment established for the cure."

Cancer and fungus *hematodes* of the testicle, Mr. R. considers as the only two diseases of that organ in which castration becomes indispensable, or even in general advisable.

In treating of the diseases of the spermatic cord, *circoele* is handled at considerable length. The complication of this disorder with a *hernia* is thus noticed:—

"The entrance of the *circoele* into the inguinal canal produces a degree of dilatation which facilitates the descent

of the omentum. Accordingly, these two complaints have been conjoined with extreme inconvenience to the patient, from the impossibility of employing the palliative practice of supporting the *hydrocele* by a truss, without, at the same time, injuring the *circoele*. This unfortunate conjunction is sometimes aggravated by the additional inconvenience of the *hernia* and *circoele* becoming united by adhesions. In this case the omentum cannot be returned without dragging the *circoele* along with it; on which account the case does not admit of palliation or of cure, excepting by an operation.

"In general, however, a *circoele* may be distinguished from a *hernia* by placing the patient on his back, and emptying the swelling by pressure upon the scrotum, then by pressing the fingers firmly upon the upper part of the abdominal ring, and desiring him to rise. If the case be a *hernia*, the tumor cannot reappear so long as the pressure is continued on the abdominal ring; but if it be a *circoele*, the swelling returns with increased size upon reassuming the erect posture, in consequence of the return of blood into the abdomen being prevented by the pressure upon the abdominal ring."

We will not pursue our analysis farther, but conclude with congratulating practitioners on the accession which this valuable little volume affords to the general stock of knowledge on an important class of diseases. It makes an agreeable, as well as useful, companion to Sir Astley Cooper's splendid work on the same subject.

MEDICAL GAZETTE.

 publicum sit, dicendi periculum non recuso."
 CICERO.

EXPEDIENCY OF CONFERRING DEGREES IN LONDON.

THERE can, we think, be no reasonable doubt about the propriety of medical degrees being granted in London. It ap-

appears little short of absurd that a student who has received the high standard of education which the metropolis affords should yet be compelled to resort to some other seat of learning for the honorary distinctions of his profession—that his knowledge should be acquired at one place, and the certificate of his attainments at another. While this continues to be the case, London, with all its substantial advantages over Edinburgh, will never be able to meet the northern capital on equal terms. The power of conferring medical degrees, then, ought to exist in the metropolis: there ought to be a *real* “University of London,” instead of the mockery of such institution which at present exists in Gower-Street.

It seems extraordinary, that with a larger number of medical students than are congregated in any other part of the empire, and with opportunities of affording instruction prodigiously greater than those possessed in any other portion of the British dominions, the highest honours of the profession should only be attainable by visiting either the English universities, where medicine cannot be efficiently taught, or by journeying to Scotland, or to the sister kingdom. The Scotch and Irish claim “reciprocity” where no reciprocity can exist. First let London be placed on an equal footing with Edinburgh, and then let the graduates of both compete for public favour on equal terms, and let the public have all the advantages of a fair and open competition.

But how is this to be achieved? The difficulty with respect to London depends in great measure upon the jarring interests which lead those connected with one establishment to oppose any proposal of conferring privileges upon another. The gentlemen in Gower-street say that their institution is an University, and that therefore they ought to have the privilege of granting degrees. The

friends of King’s College say that they have a charter,—and therefore they are the fittest parties to enjoy that power; while the teachers at the great hospitals put in their claim, and urge that it is their schools which have long since established the reputation of London with regard to its medical institutions: that the advantages they offer in practical illustrations of the principles which they teach are such as greatly to outweigh the empty distinction of a name, and that several of them being chartered bodies, and having royal endowments, might assume the title of university or college with less arrogance than a *parvenu* establishment—the offspring of a joint-stock company.

If, then, it be admitted that it is expedient to confer medical degrees in the metropolis, there yet remains the very important question—to what body ought the privilege to be entrusted? We have one institution which (as every one knows) calls itself an University, and for which a bold but unsuccessful effort has recently been made. Now without either admitting the special pleading and interested eulogy of Mr. Tooke and others, who are at once the proprietors and patrons of the establishment—or repeating, on the other hand, the terms in which we ourselves have endeavoured to laugh or lash them into a little more modesty and less pretension—we admit the school to be a good school enough, and that, if it had an efficient hospital, it would approach to a par with some of the other establishments. Yet, without any desire to decry the school in Gower-Street, we would ask, on what principles of justice or policy privileges should be conferred upon it which are denied to the other great schools of this metropolis?—much more, why privileges should be granted which would annihilate the others?—for it is quite clear, that to confer on any parti-

cular school the power of granting degrees, would at once establish a monopoly and destroy all competition. We do not know of any thing in which the establishment in question is superior to the other great schools, except the name; and if the schools in the Borough were to designate themselves the United Colleges of Guy and St. Thomas, or the Southwark University—or if our friends at Smithfield were to call their establishment the University of St. Bartholomew—there certainly is nothing in reason or common sense which should withhold from them any power as to conferring medical honours which was granted either to the London University or King's College. It is a curious, and in some respects an instructive spectacle, to see the very same men who go into parliament to denounce all other monopolies, in the same breath demand exclusive privileges for themselves—a monopoly in the disposal of degrees in science! But we have spent too much time in shewing where the privilege ought *not* to be vested, for there is no chance of its being so; let us inquire in whose hands it might with most propriety be placed.

There are three medical corporations in this country, each at the head of its respective department—the Colleges of Physicians and of Surgeons, and the Worshipful Society of Apothecaries. The Surgeons, in conferring their diploma, constitute *surgeons*; the Apothecaries constitute *apothecaries*; and why should not the College of Physicians constitute their diplomatist a physician? It is now a long period since we threw out this suggestion; which some of our contemporaries, who at first ridiculed it, have subsequently adopted as their own: but let that pass. We ask, as we did before, “why should not the College of Physicians originate physicians?” The only objections which strike us as at all plausible, are,

that it has not been customary, except for *bonâ fide* Universities, to confer degrees, and that the College in question is unpopular.

With respect to the former, it does not seem to be insurmountable; for as the Physicians have already the power of granting licenses to practise physic, though without the degree, it would not be any great stretch of prerogative, on the part of the Crown, to extend the privilege to the Doctorate. That the Archbishop of Canterbury can exercise the right of creating an M.D. shews that it is not exclusively confined to the Universities; and both Oxford and Cambridge would probably be better pleased to see it in the hands of the College of Physicians than any where else.

But the College is said to be unpopular—and we do not deny the allegation. This very circumstance, however, depending as it does upon the exclusiveness of its principles, and the privateness, if we may so call it, of the institution, would probably be removed by the changes in its constitution to which any such arrangement would necessarily give rise. It would become a new College, and, with its greater power and more extensive influence, its more public duties and higher motives would no doubt put off the vices which at present mar its character and destroy its utility. Nay, we would make assurance doubly sure, and aid its good intentions by the stimulus of necessity. The new privilege should be accompanied by new obligations, and whilst its power was established by chartered prerogative, its popularity should be secured by the liberality of the conditions. A College of Physicians raised on a solid and extended basis, with both the power and the will of conferring, on all who merit them, the highest honours in the profession, would take a place in the medical institutions of the country which the

present neither has done nor can ever hope to attain. It would be, not in name, but in truth and in fact, at the head of the medical profession—the first in influence as the first in rank.

SCOTCH APOTHECARIES' BILL.

APOTHECARIES' BILL, — Resolution reported:—

“That, before any Bill to amend the laws for regulating the practice of Apothecaries throughout England and Wales shall be passed into a law, it is desirable to inquire more fully into the subject than can effectually be done during the present Session of Parliament.”—*Extract from the Votes and Proceedings of the House of Commons.*

INQUIRY INTO THE STATE OF THE MEDICAL PROFESSION.

MR. WARBURTON,—Committee to inquire into the Laws and Regulations affecting the education and practice of the members of the Medical and Surgical Profession in the three kingdoms. [Early next Session.]—*Ibid.*

INQUEST AT COLCHESTER.

As we have been appealed to for our opinion regarding the conduct of certain parties engaged in a late inquest at Colchester, we feel no hesitation in giving it: but a mere statement of the facts, we think, will be sufficient; they carry with them their own comment—maugre the silly sophistry of a contemporary, who holds himself to be “Sir Oracle” on every thing connected with Coroners’ business.

The facts are briefly these:—A woman was found in a dying state in a street at Colchester, by night, apparently after having fallen, in a state of intoxication, from a window above. She died in five hours after. Mr. Walker, the surgeon who attended her, wishing (no doubt with the best intentions) to give the most satisfactory evidence on the inquest, opened the body and exa-

mined it. But he examined the body *before* the inquest, and naturally exposed himself to the censure of both coroner and jury for his premature interference. Mr. Abell, the coroner, has written to us a full account of the matter, in which he sets the illegality and impropriety of the surgeon’s conduct in a very clear light. We only subjoin an extract from his letter, as any thing like a reply to the Editor in question is inadmissible in these pages, and wholly superfluous. Mr. Abell evidently does not *know* the party about whom he writes.

“The circumstances of the inquest, I acknowledge, have been correctly stated; but, sir, according to the law and custom of the country, you will consider, that to deface and mutilate a body previously to a view being had of it by a jury, must necessarily tend to render of no avail the obligation of such jury to take a view of the body previous to their coming to their verdict as to the cause of death.

“That a post-mortem examination of the body was necessary, and that it is highly desirable in most cases of sudden death where an inquest is required, I readily allow; yet it is always to be done by consent of the coroner, or the wish of the jury desirous of further evidence. But to make a premature and unauthorized anatomical inspection, I contend is most illegal; and the party or parties making such inspection are guilty of a *misdemeanor*. As much as this I stated to the jury, considering it my duty so to do as coroner.

“No objection would have been made to an inspection of the body by Mr. Walker, upon his intimating that he could not give evidence as to the cause of death without it: but whether it was from ignorance of the usual and only legal course adopted at inquests, or from presumptuous and inconsiderate haste, that he proceeded to make a post-mortem examination, it was not my province to know; but having done so, it was my duty to animadvert upon the circumstance*.”

* The above letter is dated the 16th ult., and should have been noticed earlier but for a press of other matter.

LIVERPOOL INVESTIGATION.

Much interest has been excited during the last week at Liverpool, by an inquiry entered into by the Committee of the Infirmary of that town on the conduct of Dr. Baird, one of the medical officers of that institution, touching an imputed breach of professional delicacy, in examining a female patient with an alleged unnecessary degree of minuteness. We subjoin some letters respecting the case, sent to us by Dr. Baird, but we decline pronouncing any opinion on the general question, especially as it is to be further investigated by a medical jury. The only thing that strikes us as worth adding at present is, that the case was one not occurring in the Infirmary, but in Dr. B.'s private practice; yet the Committee of the Infirmary, upon what seems to us, to say the least of it, very questionable evidence, proceeded to pronounce definitively against their officer, and even went so far as to request him to resign. This method of disposing of the reputation of a medical man of some twenty years' professional standing, appears to us somewhat summary and harsh; but we trust that the medical tribunal now appointed, consisting chiefly of the officers of an infirmary in a neighbouring town, will settle the question creditably to the profession, and satisfactorily to the public.

To the Editor of the Medical Gazette.

Liverpool, July 6, 1833.

SIR,

I HAVE taken the liberty of addressing to you a newspaper containing a report of some proceedings at the Liverpool Infirmary, together with the annexed statement of the medical facts of the case, which is not there given. You will thus be enabled to form a correct judgment upon a question which appears to me to involve deeply the rights

and dignity of the medical profession, of which I am a member.

I have the honour to be, sir,

Your most obedient servant,

D. BAIRD, M.D.

Physician to the Liverpool Infirmary.

CASE of J. P. V., æt. 21.—A female patient, who has been in a bad state of health for upwards of two years, within the last six months has been gradually getting worse. She complains of great debility, her breathing is short and hurried upon slight exertion, she has a constant thirst, occasional severe headaches, painful and irregular menstruation (the catamenia having been suppressed for five months at one time), with frequent desire to void urine; her legs and feet are œdematous and painful, the veins of the right leg slightly varicose, with pains of the hip and thigh. Such was the state of this patient when she consulted me in the early part of last March. She called upon me several times, and had some active remedies prescribed, from which she received little benefit. About the end of March she first shewed me her heel, upon which there was a piece of thickened cuticle resembling a corn. At her next visit, her general health having undergone no improvement, the œdematous swelling of the feet and legs still continuing, and the patient, in addition to these symptoms, complaining of a swelling of the thigh, I thought it necessary to propose a private examination, to which she readily assented. In the course of this examination I found the inguinal glands enlarged, but there were no appearances to confirm my previous suspicions of the existence of local uterine disease. At the present time she is nearly restored to health, after a continued course of alterative medicines, with digitalis, squills, and quinine.

I beg leave also to subjoin copies of the certificates of two medical gentlemen who had an opportunity of examining into the state of the patient.

Liverpool, June 6, 1833.

I do hereby certify, that on the 23d of May last I saw J. P. V., at Dr. Baird's house, in Duke-Street, when I made a particular examination respecting the state of her health, and am satisfied that if the symptoms of her disease

were the same at the time I saw her that they were at the time she was first examined by Dr. Baird, this gentleman could not have prescribed with satisfaction to himself, with safety to the patient, or with the prospect of doing all that the case required, without making the examination that he did. I may be permitted to state, that females are disposed to ascribe all their complaints to a derangement of the genital organs, and if their medical attendant fails to make such an examination, verbal or manual, as the case may seem to require, they reasonably conclude that he has not obtained all the information respecting their disease that it was in his power to obtain, and cease to have any confidence in his treatment. I may also state, that in no particular are young and careless practitioners more severely blamed by the best writers on female diseases, than for omitting, through a false delicacy or neglect, to make that examination for which Dr. Baird has been, in my humble opinion, most unjustly condemned.

(Signed) J. CARSON, M.D.

Liverpool, June 27, 1833.

My Dear Doctor,—I recollect examining a young woman of the name of J. P. V., at your request: the right leg and ankle were swelled, and the superficial veins enlarged and varicose; there was a little thickened portion of skin on the side of the heel, which partook of the nature and appearance of a *soft corn*, and did not require surgical treatment.—Believe me, &c.

(Signed) JOSEPH CHURTON,
Member of the Royal College of
Surgeons, London.

P.S.—I saw the young person above-named some time early in May.

PETITIONS AGAINST THE SCOTCH APOTHECARIES' BILL.

Numerous petitions, we observe, continue to be presented to parliament against the proposed amendment of the Apothecaries' Act. Among those which have been forwarded to us for our notice and inspection, is the following:—

*The President and Fellows of the King and
Queen's College of Physicians in Ireland,*
After setting forth their present powers

and privileges under various Acts of Parliament, proceed to say,

“Your Petitioners respectfully submit, that any partial legislation with respect to the medical profession in these countries is liable to be attended with unexpected difficulties: the number of medical qualifications is so great, the constitution of the authorities so various, and their powers so dissimilar, that any law passed for the ostensible purpose of remedying a single grievance or anomaly, can scarcely fail to disturb the adjustment which the progress of time has achieved, and create inconveniences of still greater magnitude than those which it is supposed to redress. Your Petitioners beg leave, therefore, to submit to your Honourable House, the necessity of a parliamentary inquiry into the present state of the practice of medicine in Great Britain and Ireland, previously to the enactment of any such measure as that which is at present contemplated.”

Various objections to the measure are then stated at length: among them we find it said, “that if the Bill should pass into a law, the School of Physic in Ireland will be virtually extinguished; as from the Scotch Universities, or the Colleges of Surgeons of Great Britain, in conjunction with the Apothecaries' Company, privileges may be obtained which your Petitioners and the University of Dublin will be precluded from conferring; and this legislative monopoly will be substituted for useful competition, and with pecuniary benefit to those corporations solely at whose suggestions your Petitioners are informed the present Bill has been submitted to your Honourable House.”

And the Petitioners conclude with the following deprecatory *résumé*:

“1. That no legal alteration be made, with respect to the profession of the practice of medicine within the United Kingdom of Great Britain and Ireland, without a previous complete parliamentary inquiry as to the measures already adopted by the authorities to whom the public safety has been by law committed in the said United Kingdom at large.

“2. That any privileges which may be extended to Graduates of the Scotch Universities practising in the United Kingdom beyond the precincts of Scotland, and the immunities which, according to the proposed Act, it is intended to confer on the surgeons, assistant-surgeons, or apothecaries, of the Royal Army or Navy, or of the Royal East-India Company, be, for the reasons therein stated, conferred equally on the Licentiates of the King and Queen's College of Physicians in Ireland, and on

the Graduates in medicine of the University of Dublin.

"3. That no corporate body, except a College of Physicians or University in the United Kingdom, shall be vested with any authority (except what at present legally belongs to them) of examining candidates as to their proficiency in the theory and practice of physic, and that therefore the examinations proposed to be held by the Apothecaries' Company under the Bill, be confined to pharmacy, pharmaceutical chemistry, materia medica, and medical botany. And your Petitioners will ever pray."

(Signed) HUGH FERGUSON, M.D.

President.

G. A. KENNEDY, M.D.

Registrar.

At a numerously attended meeting of Medical Practitioners at Bath, the following Resolutions were passed:—

Resolved,—That under the circumstances of the profession in 1815, when no provision existed for insuring the adequate qualification of general practitioners, the Act of Parliament passed in that year was a necessary and salutary measure; and that the manner in which it has been carried into execution by the Apothecaries' Company has tended to serve the public and promote the respectability of the profession in this kingdom, by raising the standard of medical education, and checking the intrusion of unqualified persons.

That the proposed alteration of that Act, though purporting merely to permit the graduates of Scotch Universities, the licentiates of Scotch Colleges of Surgeons, and medical officers of his Majesty's and the East India Company's Services, to act as general practitioners in this country, would virtually nullify the powers now exercised by the Apothecaries' Company, and would consequently deprive the profession and the public of the advantage and protection they have hitherto enjoyed.

That the privileges now sought by Scotch physicians and surgeons are not conceded to the members of the London College of Surgeons, who are compelled to obtain the license of the Apothecaries' Company, in order to qualify themselves to act as general practitioners.

That this meeting, therefore, whilst it disclaims all desire for monopoly, or to exclude from general practice in this kingdom properly qualified persons of any class, protests against the proposed bill, as founded on a partial view of the question, and as calculated to aggravate the

embarrassments already experienced from the anomalous and ill-regulated condition of the various branches of the profession.

That petitions be presented to both Houses of Parliament, deprecating on these grounds the measure now in progress, and calling for full and general inquiry in all departments of the profession, as an indispensable preliminary to safe or judicious legislation on any part of the subject.

[The petition being to the same purport as the resolutions, we deem it unnecessary to insert it.]

MIDDLESEX HOSPITAL.

Source of Hæmorrhage from Ulcers of the Posterior Fauces.

JOHN WEBB, ætat. 27. was admitted a month ago into the Middlesex Hospital in the last stage of phthisis: he lived three weeks after his admission. This is the patient in whom Mr. Mayo tied the right common carotid artery for hæmorrhage from a venereal ulcer in the posterior fauces. The hæmorrhage did not recur after the operation. The case is detailed in the London Medical and Physical Journal for December 1829.

It was supposed at the time of the operation that the hæmorrhage proceeded from the lingual artery. The postmortem examination of the body has shewn this conjecture to have been correct. The right lingual artery is small, and half an inch only in length, and terminates by adhering to the cicatrix of the ulcer in the throat. The other branches of the external carotid are in their natural state.

In Dr. Watson's case, recorded in this journal, of fatal hæmorrhage from an abscess opening into the pharynx, which occurred at the Middlesex Hospital not long before the case of Webb, the bleeding proceeded from the same artery. The cause of the uniformity in the source of the bleeding in such cases is the exposed situation of the lingual artery towards that surface of the posterior fauces which is the frequent seat of ulceration. But it must be remembered that both the inferior thyroid, and the fascial arteries near their commencement, are placed so close upon the same surface as to make it likely that bleeding, following ulceration of the throat, may sometimes proceed from one of these vessels instead of from the lingual.

The carotid artery, in the instance of Webb, is obliterated, and has been ab-

sorbed for the extent of an inch and a half. This is about the extent to which it was found to have disappeared in the case of a patient, narrated in the Medical Gazette, in whom the carotid was tied for a varicose state of a branch of the temporal artery. The preparations taken from the three cases here adverted to, which were examined at the Middlesex Hospital, are to be seen in the anatomical museum of King's College.

Fungus Hæmatodes of the Head of the Tibia.

John Brown, ætat. 35, a shoemaker from the neighbourhood of Eltham, was admitted, under the care of Mr. Mayo, on Tuesday, June 18. His left leg has been deformed and wasted from birth. The right leg, ten weeks before his admission, became affected in the following manner. Without any assignable cause, pain and swelling began at the ligamentum patellæ. The swelling increased rapidly, and the pain was at times extremely severe. The skin was not inflamed. On the 11th of May a surgeon introduced a lancet into the swelling upon the inside of the ligament of the patella. Nearly a pound in weight of, curdy or medullary matter came away through the opening. The pain was considerably relieved by this operation.

When the patient was admitted on the 18th, there was a gaping orifice, an inch in length, where the incision had been made, from which a bloody sanies issued. A probe, introduced into the opening, appeared to reach the back part of the tibia without distinctly touching, or grating upon a bony surface. The enlargement of the knee seemed confined to the head of the tibia. The condyles of the femur and the patella seemed in their natural state, and the synovial membrane of the joint was not distended with fluid. The leg could be bent inward or outward at the knee-joint. The swollen head of the tibia was drawn rather behind the condyles of the femur to the same degree as in aggravated cases of ulcerative disease of the knee. The patient's complexion was sallow; his tongue inclined to dryness; the pulse frequent. Some opening medicine was given, and an opiate at night.

On the 20th the limb was removed by amputation above the knee. The patient has gone on favourably, and the stump is healing. The pulse, however, was unusually frequent, not less than 150 at each visit for the first five days after the operation: it is now 110.

Upon an examination of the head of the tibia, the bone was found to have been absorbed, in consequence of the growth of fungus hæmatodes in the cancelli. In

place of the head of the bone, there was a strong membranous cyst, filled with fungus. In the membranous cyst some remains of bony substance were found. The fungus was, for the greater part, of a dark red, intersected with streaks of yellow medullary substance: the latter substance filled the sound cancelli of the bone to nearly the middle of the bone.

In the amputation a double circular incision was made: the first through the integuments and fascia; the second through the muscles. Mr. Mayo attributed to Mr. Guthrie the observation that the fascia should be cut through in the first, and not in the second incision; and as the reason, shewed upon the separated limb that the fascia may be dissected back from the muscles much more quickly than the skin from the fascia.

The muscles were of an unwholesome colour, having a slightly livid tinge; they were flabby, and did not shew much disposition to retract. Mr. Mayo remarked, as a circumstance which had surprised him when he first noticed it, that wasted muscles in extenuated limbs retract upon division in a much greater degree, both at the time and afterwards, than large and strong muscles. In extenuated persons the integuments retract little, the muscles to an indefinite extent. In strong and vigorous persons these points are reversed, so that the surgeon, unless he has calculated upon them, is often in the latter case embarrassed by the disproportionate quantity of muscle which he has preserved.

The medullary artery of the bone in this instance bled considerably; it was touched with a hot iron, but without arresting the bleeding; it nearly stopped upon lint being pressed for a few minutes against the end of the bone, and a strip of the adhesive plaster was then applied in such a manner as to press the upper flap of integument and muscle against the end of the bone. There was no secondary bleeding.

Mr. Mayo recommends in amputation of the thigh the double circular incision as the most rapid method, and as producing the fullest and most fleshy stump, and the approximation of the edges of the wound in a transverse line in preference to a vertical line. In the latter method the stump has to rest against a corner of the incision, which often leads to a collection of matter at that part.

Compound Fractures.

In cases of compound fracture of the leg, and of the humerus, treated in the Middlesex Hospital, Mr. Mayo has lately used, with evident advantage, the application of pounded ice during the ten days following the accident. The ice pounded,

and laid in a bladder upon the part, is agreeable to the sensations of the patient: it allays the pain and uneasiness in the part, and seems to prevent inflammation.

PREPARATIONS OF ARSENIC,

EMPLOYED

By M. DUPUYTREN,

In the Treatment of Malignant Ulcers.

THE arsenical preparations in common use act as escharotics, and often leave behind them deformed cicatrices. M. Dupuytren believes that he is able to obviate these inconveniences by a combination of calomel and arsenic, in proportions different from those usually adopted. His formula is the following:—

R White Arsenic, or Arsenious Acid,
4 parts.
Calomel in powder, 96 ditto. M.

The arsenic may occasionally be increased to 5 or 6 parts in the 100. The ulcerations are well cleansed with poultices, in the first place; then, with a little piece of charpie dipped in the powder, a layer is put on, not exceeding a millimetre in thickness. The whole of the ulcer is covered, if it be but moderately large; but if considerable, it must be only half or quarter covered, according to its extent, taking care to apply the remedy on successive occasions to different parts of the sore.

M. Dupuytren also employs a paste, composed of a solution of arsenious acid in distilled water, with calomel added, and sufficient of powdered gum to give it the consistence of a paste. The proportion of arsenic in the paste is greater than that in the powder, being 6, 8, 10, or 12 hundredths of the acid to 91, 92, 90, or 88 hundredths of the calomel respectively. It is applied with the same precautions as the powder.

The application of both the paste and powder produces, in the first instance, pain and inflammation; but these effects subside, and the remedy may be repeated eight or ten days after. Five or six applications generally cure an ulcerated surface. No eschar is formed during the process, the surface is merely modified without being cauterized, and in this consists the superiority of this method of treatment over that of Frère Côme and Rousselot.—*Gaz. des Hôp.*

THE CONCOURS AT PARIS.

THE contest for the chair of *Clinique Interne* has at length closed: M. Rostan has been appointed. Never was such a mess of jarring confusion as this whole business.

QUERIES RESPECTING CHOLERA.

A CORRESPONDENT requests our insertion of the following queries. We shall, of course, be happy to receive well-authenticated replies to them.

1. Have the limbs of persons dead of cholera been observed to move elsewhere than at Tipton?

2. Have oily dejections been noticed in cases of cholera?

3. What are the powers of mercury in the complaint? How are they displayed, and in how short a time after its employment?

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE STOMACH AND
INTESTINES.
—

MORBID APPEARANCES.

BEFORE I commence the consideration of particular diseases of the stomach and intestines, it may be advantageous to give a short general account of the morbid appearances observed in this part of the body. But in the first place I shall direct your attention to the varieties which are observed in the natural state of the parts, according to the portion of the canal which you examine, and according to the age of the patient.

Natural Appearances.—In the first place, you are to remember, that if you examine the inner surface of the stomach and intestines of a living animal that is making no effort at all, so that its circulation is perfectly free, it is rather redder than the inside of the cheeks—the mucous membrane of the former is rather redder than the mucous membrane of the latter. In some animals, after death, you will find the mucous membrane pale, or at the utmost only slightly coloured; but here, again, much depends on the mode in which the animal dies. If you kill it by asphyxia—that is to say, if you kill it by putting a stop to respiration, these parts will become of a very red colour, or very dark, and there will be great congestion of blood; but if, on the other hand, you kill the animal by hæmorrhage, these very parts will look paler than they were during life.

294.—XII.

The inner surfaces of the body are liable to exactly the same changes of colour as the external. You know that, if a person die from strangulation, the surface of the body will perhaps be of a dark colour, more or less red; whereas, if he be bled to death, he will become pale. Now we are to generalize these changes, and be prepared to expect circumstances quite analogous in the inner surface.

Causes of increased redness.—Then, if we look at the stomach during digestion, or if we look at the upper part of the inner surface of the small intestines during chylification, when their great function is going on, we shall find the parts redder than at any other time. This, of course, will occur at different periods of the day, according to the shorter or longer time that has elapsed since food was taken into the mouth. Any obstruction to the return of the blood will make these parts redder than they should be, and perhaps darker. Hæmorrhage may take place from the inner surface of the stomach, or from the inner surface of the intestines, from the great accumulation of blood; and as impediments to the circulation are very common just before death, you more frequently than not find these inner surfaces red and dark-coloured—at any rate partially.

Colour influenced by the decomposition and situation of the body.—I believe I mentioned formerly, when speaking of the deceptive appearances with regard to inflammation, that you may produce these changes at your pleasure, accordingly as you examine a body a longer or a shorter time after death, having first placed a certain part in a dependent situation, so that the blood may gravitate in a certain direction. If you place a certain portion of the intestines in a dependent situation, lower than the rest, the blood will of course gravitate to it; and if you allow a long period to occur before you examine them again, according to the length of that period—

2 L

cæteris paribus—the situation of the parts, and the quantity of blood in the body, will you find them darker.

From the natural arrangement of the parts, you will generally find that those portions of the intestines which are in the pelvis are of a darker colour than the others; and you find that the posterior surface of the stomach is darker than the anterior, merely from the gravitation of the blood; and of course darker and darker will the appearance be, according to the length of time before you make the examination. If the examination be delayed for a great length of time, so that decomposition takes place in any degree, and the blood is allowed to transude from the blood-vessels, through the different coats, you will see extensive patches of red, and you will see stains along the course of the veins, just as you observe on the external surface; and if a still longer period transpires, you will have the whole of the parts red together. If the blood completely transudes from the vessels, it will dye the whole substance; and from the solid portions being decomposed—melted down into a mass, you will actually find more fluid than the blood itself will afford.

Natural colour at various periods of life.—In persons in whom the intestines have been diseased during life, you will find them of a paler hue lower down than higher up. The lower down you examine them, the greater generally is the paleness. They are also pale in youth, and in the young adult period; but in the fœtus these very parts are naturally of a rosy hue, and in old age they are of an ash colour, and not only so but the veins are seen to be very large. These are the chief varieties as to colour.

Relative thickness and consistency of the mucous membrane.—But we must recollect that there are different appearances likewise in regard to thickness; that the mucous membrane is naturally thickest in the duodenum, and thinnest in the colon; and that the mere circumstance of an accumulation of blood just before death, or after that event, will occasion it to appear thicker than it should be without any disease of that particular part; while it always appears thinner in persons who die in a state of anæmia, who are bled to death, or who have not rallied a little for some time before death, or who die suddenly emaciated. There is a great difference too in the consistence of the mucous membrane in different parts: generally those which are by nature thickest are also by nature firmest.

At the pyloric end of the stomach you will find the mucous membrane always thicker in health, and more consistent, than at the other extremities; and it is a natural circumstance for the mucous

membrane to peel off in the largest portions from the inner surface of the stomach.

Consistency influenced by the period at which it is examined after death, &c.—The consistency of the mucous membrane varies according to the time at which you make the examination; it always becomes less in proportion as time elapses after death, and more particularly if the surface of the stomach be exposed to the air. If it have immediate contact with the air, it loses its consistency much quicker than it otherwise would.

Influence of the gastric juice.—It is also exceedingly variable according to the quantity of gastric juice which the stomach contains; for it will soften the inner surface, and indeed the whole stomach. This softened state has been seen very frequently in persons who have died in perfect health. Where they have been suddenly destroyed by mechanical violence, or by any violence not acting till the moment of death, the mucous membrane of the stomach has been found softened; whereas, in persons who have been weak, and in whom you would suppose such softening might occur from disease, you continually find no such appearances. It has also been found, that not merely the mucous membrane, but the whole of the coats of the stomach together, have been softened under these circumstances, and even perforation has taken place, and still farther effects have been observed in the viscera, by its immediate contact with the part in which perforation took place. It was on this account supposed by John Hunter, that the gastric juice will not act on a living part, but that it has the power of acting on dead animal substances, and therefore will act on the stomach when life is no longer able to resist it. There has been a great difference of opinion on this point. When it was first promulgated it was doubted—it was afterwards believed; but many French writers again doubt it, though I believe we have no good reason to suppose it doubtful, when you consider that the parts of the stomach with which the fluid comes in contact are softened at the same time; and it is singular that this softening particularly takes place at the posterior part, where the gastric juice must chiefly have gone. Thus we may have considerable morbid appearances without any previous disease, simply from the effect of the gastric juice; at least, it is considered, that when the stomach is softened, whether the individual was in health before, or died from an affection of the stomach, and whether it is at the posterior end of the stomach or not, and whether at the perforation the parts are rubbed off or not, we may be justified in saying that the appearances are the effect simply of death.

Hypertrophy of the mucous follicles.—Many

morbid appearances in the intestines take place, particularly in the mucous follicles. Now we are to remember, that in children the mucous follicles are more distinct than in adults — proportionately. You will remember, in regard to hypertrophy of the heart, I mentioned that the walls of the left ventricle are naturally thicker in children than in adults, and many parts in children have been supposed to be hypertrophied when the greater proportionate thickness of them was simply a natural circumstance. Now the mucous follicles, as I have observed, are much more distinct in children than in adults; in fact, in adults in health they are not particularly seen excepting in the cæcum and duodenum, and sometimes, again, at the lower part of the ileum; but in children they are generally distinct enough through the length and breadth of the intestines. These mucous follicles are often seen to be very large after diarrhœa, and other diseases which are attended by an irritation in the alimentary canal; but sometimes they certainly are very large without our knowing that the individual had suffered any previous disease of the alimentary canal.

Inflammation may not leave redness after death.—There can be no doubt that a degree of inflammation may exist in the alimentary canal during life, and leave no marks after death. It may happen that the bleedings which were instituted have taken away the redness of the part, and left it perfectly pale, although the powers of life were destroyed by the disease, and in some cases by the remedies; but it is possible for the disease to kill, and yet no redness may be discovered after death. We see a similar occurrence upon the surface of the body, when patients have had erysipelas at the time of death. It is not uncommon to see the parts far less red than during life; and perhaps they are not red at all. Again, we see that redness may exist in all these parts without any inflammation whatever—that it may be the result of decomposition, or of some mechanical impediment. If the redness be of an inflammatory nature, or if it have been produced by inflammation, it ought to exist in the minute vessels; but still it is to be remembered that redness may occur there as well as in the large ones, from mechanical obstruction. If the redness exist only in the larger vessels, it is mere congestion, which may arise from many causes independent of inflammation. If you see mere over-distention of the large vessels, that cannot be considered inflammation—if it be, it ought to exist in the minute vessels; but still, although it does exist there, that is not a sufficient reason for its being inflammation. When

the redness arises from inflammation, the large vessels may be over-distended too; but in inflammation, the small vessels are first overcharged, and ultimately the large; whereas, in mechanical obstruction, the large vessels are first overcharged, and ultimately the small.

Parts which the redness may affect.—Now in regard to redness, it may affect the mucous membrane simply in its continuous surface, it may affect the villous coat, it may affect the follicles, or it may affect two or three of these parts together. If it affect merely the villous coat, you have simple red points, and it is in the stomach and lower part of the ileum that you chiefly find this inflammatory redness. This redness is of all degrees of shade. The villous coat may be transparent or not. If it be the follicles which are inflamed and red, there are frequently red circles around them, and perhaps also on the summit. Then if these widen and form a border, you have the follicles of an uniform redness.

Hypertrophy and induration of the mucous membrane.—The mucous membrane is sometimes found thickened, and sometimes it is firmer than usual, and will peel off in large portions. If this occur anywhere, it is sure to be met with in the stomach and large intestines. When it is hypertrophied, sometimes it is as smooth as usual; but sometimes it occurs more at one spot than at another, and you will have the mucous membrane exceedingly rough—that is to say, the hypertrophied parts being very partial, the membrane becomes rugged; it is polished enough, but still it gives a feeling of ruggedness; it has depressions and elevations. Sometimes the hypertrophy is such, that portions hang into the canal; you have it really in processes. When it is hypertrophied there are various degrees of consistency, and various degrees of colour. Sometimes with the hypertrophy there is great irritation, and a great accumulation of blood. Occasionally you will have hypertrophy of the villousum, and sometimes only of the follicles; the follicles will be enlarged. When the latter occurrence takes place, sometimes the orifices of the follicles will diminish; and if they diminish, they will at last close, or nearly so, and then the secretion accumulates beneath, and dropsy takes place. If the contents happen to be solid, of course you cannot apply the word dropsy; but the follicles are distended with a soft, thin, carious substance. Occasionally the mouth of the follicles increases very much; sometimes they increase by ulceration, and these overgrown follicles are generally seen, like all other morbid appearances, at the lower part of the ileum, where the ileum ends in the colon.

Hypertrophy of the sub-mucous cellular membrane.—Sometimes it is not the mucous membrane which is hypertrophied, but the cellular membrane under it—the sub-mucous cellular membrane; and occasionally it becomes very bulky, or very hard, and falls into a state of scirrhus, and becomes as hard as cartilage. The disease which is called scirrhus, a specific induration and hypertrophy, frequently takes place. Sometimes when it has begun there, the membrane on the other side becomes hypertrophied too; but I believe that when scirrhus affects the alimentary canal, it is the cellular membrane under the mucous membrane which is first attacked. The other coats will sometimes remain healthy for a great length of time, but hypertrophy, ulceration, and other diseases, may take place.

This particular affection of the sub-cellular membrane is very commonly seen at the pylorus, but it seldom takes place except after the middle period of life has passed. In this affection it is common for the orifice of the pylorus to lessen; and the stomach behind frequently acquires an immense size in such a case as this. If hypertrophy and induration, true scirrhus, takes place in the small intestines, it generally gives rise to stricture; the canal of the intestines where it may be situated will be diminished, so that stricture is the consequence. You may have a stricture from other causes, but this is a frequent source of it. This change is rarer in the small intestines than in the stomach, and rarer in any part of the large intestines than in the rectum; the rectum comes next to the stomach in point of frequency of this affection.

Atrophy of the alimentary canal.—Occasionally the reverse change takes place; instead of the alimentary canal being hypertrophied, it will become atrophied—become much thinner than natural. The coats will waste away—I do not mean be destroyed—but they will become thinner and thinner, so that the alimentary canal becomes quite transparent. Atrophy most commonly occurs at the splenic end of the stomach, and next to that at the lower end of the ileum.

Softening.—Then, again, these parts sometimes soften; and it is the mucous membrane which is most frequently the seat of this disease; it will become quite pulpy. There are all degrees of softness, till it is absolutely lost; and the disease exists in various directions. When the mucous membrane becomes softened, sometimes the colour is quite natural, sometimes it becomes pale, sometimes it is a dead white, and sometimes it is blue, just as you will recollect is the case in the brain. I pointed out that when the brain is softened,

there is sometimes great blueness of the parts all around. The change of colour in the intestines is sometimes produced by the loss of vital energy, and sometimes it is the result of inflammation. This softening is very common after chronic diseases—after phthisis, for example; and sometimes, where we find this to have been very great, there has been nothing more than anorexia, loss of appetite, and some degree of indigestion. It is common to find this state where persons have been dyspeptic.

This affection is in other respects similar to the softening of the brain. Occasionally it is acute, takes place rapidly and suddenly; and occasionally it appears to be a very chronic change. When it takes place as an acute affection, there is generally a red tongue and vomiting; but sometimes I have seen it where the patient a short time before was in perfect health. The same circumstance has been observed both with regard to the stomach and intestines. Sometimes in the case of the intestines the disease follows diarrhoea.

Gelatinous softening.—Now this softening, though it is most usual in the mucous membrane, may extend to all the coats, and the intestines may look just like jelly. At first sight they may appear healthy, but when you come to examine them, you find them like so much jelly. This general softening of the stomach is most frequent in the splenic end, and I presume that very frequently it really is the result of the operation of the gastric juice; but that, I imagine, is only one cause of the disease. Cruveilhier has given some good representations of this disease. In these cases you may brush the membrane all away. This softening is not to be ascribed to any decomposition of the part. In the case of the stomach, no doubt it will arise from the gastric juice; but if it occur in other parts of the alimentary canal, it must be supposed to have taken place during life; for the intestines do not become soft by decomposition unless a considerable degree of time has elapsed. The brain will soon become soft, but the intestines retain their consistency for a considerable time.

Experiments with Gastric Juice.—Some experiments were made at Stuttgard, in 1818, (at least cases were published there,) upon the effect of the gastric juice in producing this softening; where animals were examined before putrefaction had taken place, and the softness was seen in many cats and dogs, so that it appeared to arise from the gastric juice. If they were allowed to remain till putrefaction had taken place, even then there was not more softening than in those which were examined sooner. The fluid taken from the inner surface of the stomachs of two children who had died with this softened state

of the mucous membrane, was introduced into the stomach of some dead adults, and it soon caused a solution of the solids; whereas, when it was put into the stomach of a live rabbit, it had no effect. I consider this a great confirmation of John Hunter's opinion—that this softening of the stomach is mainly attributable to death. But it is said, that if the eighth pair of nerves was divided so that the powers of the stomach were impaired, then the gastric juice occasioned softening exactly as it did in dead animals. If these experiments were correct, they were exceedingly curious.

Softening sometimes the result of Inflammation.—There can be no doubt that common softening of the stomach and alimentary canal is sometimes the result of inflammation, because we see symptoms of gastritis during life, and we see signs of inflammation after death. But gelatinous softening of the stomach is frequently seen in children who have not suffered from inflammation, but who have been in a general ill state of health—who have been weaned when they were not able to bear it, and who have not been supplied with proper food afterwards. Thus it appears occasionally in a cachectic state, and very often the parts all around are perfectly healthy.

Ulceration.—I will now say a few words respecting ulceration of the alimentary canal. This is found most frequently in the two lower fifths of the ileum; and with respect to the large intestines, it is seen more frequently in the cæcum than in other parts. It is seen more frequently in the stomach than the jejunum or duodenum, but it is seen in all parts of the ileum more frequently than in the stomach, and it is seen more frequently in all parts of the large intestines than in the two upper fifths of the ileum. This ulceration may exist in the centre of inflammatory spots, or in the centre of red patches. Sometimes we find diffused redness. A long tract of the intestines will be red, and we observe ulceration here and there. Occasionally ulceration occurs in parts more or less melted down, and frequently it takes place in hypertrophied follicles—both the solitaria and aggregata.

With regard to the solitaria, when they enlarge and do not discharge their contents, they become distended and are more or less firm, so that they acquire a conical appearance; they then lose their conical form and have a central depression on their top, exactly like a variolous pustule. Their orifices sometimes simply enlarge, sometimes they ulcerate down merely to the level of the mucous membrane, and sometimes they ulcerate below it; and then, if they run into each other, you have a frightful ulceration. Of course the ulceration

may go on till the alimentary canal is perforated—till there is a way through it into the cavity of the peritonæum. Ulceration, like softening, may be an acute or chronic affection.

Occasionally we see ulceration in the midst of gangrene. Gangrene is a rare occurrence in these parts, but occasionally there is ulceration and gangrene all around.

Sometimes we see ulceration of scrofulous tubercles. There are scrofulous tubercles deposited under the mucous coat in the cellular membrane, and sometimes we see them under the peritoneal coat and cellular membrane. In this situation they will enlarge, ulcerate, and go through the same process as in the lungs. It is rare to find them ulcerate outwards toward the peritonæum, but I have seen a few instances of this occurrence. Most frequently the tubercles ulcerate through the mucous membrane into the intestines. This is sometimes seen in phthisis. There has been a minute abscess in the cellular membrane under the mucous, and the latter has ulcerated through.

Ulceration is seldom the effect of acute inflammation of the stomach, but it is a common result of inflammation of the intestines. The ulceration is sometimes solitary; you see only one ulcer, but sometimes there is an infinite number; in the stomach, however, they are seldom numerous. They are of all sizes, and they take all directions; some extend down the course of the canal, and some transversely. Then, as to the edges, you find them just as various. Sometimes they are natural, sometimes they are very thick, sometimes they are very hard, and sometimes they are very soft.

The nature of both ulcerations depends upon the depth of the ulcer. If only the mucous membrane be ulcerated through, the case is very different from what it would be if the cellular and muscular coats were ulcerated too; for then you would have peritonitis. There is no proportion between the depth and the length of the ulceration.

The intestine between the ulcerations is in all conditions. Sometimes it is healthy, sometimes it is unhealthy. Not only the mucous, but the cellular coat underneath, varies much as to its condition.

Now there is no doubt but that these ulcers will heal just like ulceration in other parts of the body. You will every now and then find an ulcer in the intestines in various stages. Some are open ulcers, some are half cicatrized, and others are entirely cicatrized. You will find portions of the intestines which have evidently been in a state of ulceration, but which have healed; and it is very interesting to

meet with an ulcer half healed, for then there can be no doubt of the nature of the affection.

Perforation. — Persons are sometimes found, after death, to have an ulceration in the intestines, or stomach, who were not known to be particularly ill during life. They have had some little illness, but perhaps no one knew of it—they were in apparent health when they were suddenly seized with violent pain in the abdomen, and have died from perforation having taken place and peritonitis having been set up. Occasionally this takes place where the patient is labouring under some other disease, that disease not having been known to exist in the abdomen; but more frequently it occurs where persons have suffered a gastro-enteric affection. Mere softening will produce a perforation, just as ulceration will do; and sometimes a slough will give rise to the same circumstance, though that is very rare.

In brutes, perforation has taken place, or the coats have sometimes lost their continuity by distention, occasioned by gasses. In horses it has been known to take place in consequence of vomiting, because vomiting will not occur in them unless there be such a violent effort as is dangerous to animal life. It has occurred in human beings when the stomach has been diseased: if the stomach be thin, mere vomiting has sometimes caused perforation.

Perforations from these various causes are seen most commonly in the stomach and the lower end of the organ. There can be no doubt that some perforations take place after death, but when they do not, there is generally violent peritonitis.

Blows on the abdomen will sometimes rupture the stomach and intestines. You would suppose, that in all cases where violent peritonitis took place from this circumstance, the contents of the stomach would be effused; but that is not the case. It is said that sometimes (but I believe the cases must be very rare, at least I have never met with one) very little irritation has been produced, and only chronic peritonitis. Sometimes the opening has been completely blocked up by nature, through a piece of omentum or something else, and no mischief has occurred. Sometimes adhesions have taken place, and a fistulous opening has been the consequence, so that some persons have discharged the gastric juice from their stomach, while others have had an artificial anus. You know that, in the case of the rectum, these perforations will occur, and we have what is called *fistula in ano*. Sometimes one portion of intestine will perforate into another. Two portions lie together, nature produces an adhesion, the one becomes perforated, and an opening takes place

into the fellow convolution. Occasionally the intestinal canal has been seen perforated from without. When an abscess occurs in the liver, or a stone from the ducts or gall-bladder has got into the intestines, these parts will become perforated from without. Various tumors have been known to ulcerate into the intestines.

ACUTE GASTRITIS.

Symptoms. — Gastritis, or inflammation of the stomach, is characterized by an acute and constant pain at the pit of the stomach. This pain is increased on the slightest pressure, and it is likewise increased on swallowing any thing; particularly if it be hot, or acrid. There is generally also, provided the disease is violent, a great sense of tightness across these parts. These symptoms arise simply from the locality of the inflammation, but there are others dependent on the function of the part which is inflamed. You have nausea, retching, and even vomiting itself; especially when any thing is swallowed. Sometimes you have also hiccups — singultus. There is generally experienced a burning sensation, which, for the most part, extends from the œsophagus, and is felt even in the pharynx. It is not uncommon for the epigastrium itself (the external portion of that part of the body in which the inflammation resides) to be hotter than the rest. There is generally thirst, great anxiety, and not unfrequently a feeling of great debility. The pulse is quick, small, and perhaps hard; but of course there is a great variety in this respect, just as you observe in inflammation of other parts.

Duration. — The acute form of gastritis, if it be violent and not speedily remedied, soon proves fatal.

Frequently preceded by Spasms. — You are carefully to remember that very frequently this disease is preceded by merely a spasmodic pain of the part. It is not uncommon for persons (as I shall mention particularly when speaking of what is called “disorder of the digestive organs.”) to be seized with sudden pain at the pit of the stomach, running through the back, affecting respiration, drawing the patient together, relieved perhaps by pressure (at any rate not increased by it), unattended by a sense of heat, but, on the other hand, perhaps by a sense of cold, unattended by any great thirst; and so far from the pain being increased by heat or stimuli, generally it is diminished.

Now this is evidently a state of spasm; but after it has existed for a longer or shorter time, it very frequently (if it be not remedied, or if it does not cease spontaneously) degenerates into, or gives rise to, or is followed by, inflammation of the

part. You will then find the treatment you were at first adopting highly improper: the administration of stimuli does harm, and if you omit the common treatment of inflammation, the patient is very liable to slip through your fingers.

You are therefore carefully to remember that you may have two descriptions of pain attacking this part of the body—the one entirely spasmodic, the other inflammatory; but that the spasmodic very frequently terminates in an inflammatory state.

Causes.—Gastritis is produced, in the first place, by the common causes of all inflammations—cold applied to the body, especially when the body is heated; sometimes cold applied to the inner surface of the stomach when the body is over-heated. Sometimes, when a person is very hot and takes cold drinks, before inflammation comes on there is a state of extreme debility; occasionally the power of the stomach seems almost destroyed, the person is very faint, the pulse is small, and sometimes death ensues without any reaction taking place. You will hear of ladies dying suddenly when they have been drinking cold water, or eating ices, while they were hot. The danger does not arise simply from being hot, for the hotter you are the more good does cold do; but from the person being exhausted. It is not even the simple circumstance of sweating that makes it dangerous for a person to go into the cold bath, or to roll himself in the snow, which the Russians do when there is no necessity for it; but it is the circumstance of the individual being exhausted that makes the extraction of all stimuli dangerous. If you meet with a patient who has an affection of the stomach from exhaustion, the best mode of treating it is to give a large dose of opium, together with stimulants. If the person recover from this state, it is possible that inflammation may not arise. But sometimes, without such a depression as this, the application of cold to the surface when the body is exhausted, may produce inflammation, just as in other cases. The external application of cold may produce inflammation of the bowels. Occasionally gastritis is produced by the sudden cessation of gout. When gout suddenly ceases in an extremity, inflammation of the stomach will occasionally arise, and that of a very dangerous character. But another state of the stomach is frequently induced under these circumstances, viz. a violent spasm of the part—gastrodynia; a state to be treated perhaps by brandy. Gastritis sometimes occurs sympathetic with an affection of the kidney; when the kidney is severely affected in various ways. When a stone is on its passage from the kidney, the sto-

mach generally sympathises so that vomiting occurs, and sometimes real gastritis takes place. It will sometimes arise from sympathy with the state of the womb. The womb, when diseased, frequently gives rise to nausea and vomiting, and sometimes the irritation may amount to inflammation. This state is very often induced by the passions of the mind: a sudden emotion of the mind, of a very disagreeable character, great grief, sudden surprise of an unpleasant description, a sudden and severe shock, will sometimes give rise to a spasmodic pain here—to what is called *spasm of the stomach*; and sometimes to actual gastritis. Great fatigue will have the same effect. Of course it is a disease that is easily produced by any acrid matter. Many poisons, properly so called, produce inflammation of the stomach; but any acrid matter whatever, or any stimulus properly so called—such as a large dose of cantharides or corrosive sublimate—or any thing else that can irritate the stomach, may of course produce gastritis. It occurs likewise in other diseases. In fevers, gastritis of more or less intensity is very common. You will recollect I mentioned, that in the fevers of hot countries there is burning heat at the pit of the stomach, deserving the name of active acute gastritis.

Morbid Appearances.—On inspecting the stomach after death, the redness is very seldom universal; it is very seldom that the whole of the inner surface of the stomach is inflamed. Sometimes this is the case, but generally it only takes place at a particular part. When peritonitis exists, that portion covering the stomach may be inflamed the same as any other part; but in general gastritis, properly so called, independent of inflammation of the peritoneum, merely produces local effects of the mucous membrane of the stomach, though occasionally it extends to the cellular membrane between the coats. This disease very seldom induces gangrene—I never saw myself such a thing; but occasionally gangrene does take place. Very seldom does it produce abscess; but occasionally an abscess has been found between the coats of the stomach. You are more likely to meet with gangrene of the stomach after acrid substances have been applied, than under any other circumstances. If caustic substances have been taken, then you may expect gangrene; a slough is produced, which may or may not be thrown off.

Cautions in forming an opinion as to the Cause.—You must carefully remember that this disease may arise from acrid or poisonous matters, and various substances, introduced into the stomach, without your being able to discover any trace of them. It is very possible for a patient to have vomited every thing which he took, or for

the ingredient to have passed into the intestines, and so to have escaped from the body, and yet inflammation may have been induced sufficient to destroy life. Although it is very possible that death may ensue from things taken into the stomach, yet you are never justified in saying that inflammation of that organ—that the various morbid appearances which you see there, have been owing to poison, unless you prove its presence—unless you discover it in what has been vomited—unless you find it contained in the alimentary canal, or in what is discharged, or in a vessel, of the contents of which the patient clearly partook. If it were not for an accurate knowledge of this circumstance, you might suspect that poison had been taken without there being any justifiable reason for it whatever; for the appearances within the stomach may be precisely the same as those induced by taking poison or any injurious matter, when it is simply common inflammation and the effects of it.

Treatment.—As to the treatment of the disease, the first point is undoubtedly to discover the cause. It is of very great importance to know whether the disease has arisen from any thing taken into the stomach or not, because, if it have, your first object must be either to effect its removal or to neutralize it—to destroy its power. I need not say that the most ready mode of emptying the stomach is to employ a stomach-pump: this is much better than giving an emetic, because emetics add to the irritation, or they may fail. The most powerful medicines are those of an acrid kind: sulphate of copper is one of the best; and next to that, sulphate of zinc. These operate immediately, and produce little nausea. Ipecacuanha produces great nausea, and may not effect the purpose after all; at least there is less probability of its succeeding than sulphate of copper. When you have recourse to the stomach-pump, it would be as well to employ an antidote. If a poisonous acid have been taken, it is better to pump in magnesia water than plain water; but if an alkali have been swallowed, then you should have recourse to diluted vinegars. The best plan, in all cases, is to fill the stomach with warm water—to pump it in and pump it out till the fluid comes out quite clear, and you are satisfied that nothing remains.

Provided a stomach-pump is not at hand, an emetic should be had recourse to; but notwithstanding you have done all this, and emptied the stomach immediately, you will find it of the utmost importance to go on treating the gastritis as though you had done nothing of the kind. After arsenic or corrosive sublimate has been taken, and the stomach has been washed out, and there is no fear from the imme-

diate effects of the poison, gastritis may nevertheless exist and destroy the patient, (at any rate produce great danger,) and you must have recourse to the common treatment of gastritis.

When the disease arises from simple cold, or after poisons, it may be necessary to bleed generally or locally. Cupping can hardly be borne, but leeches should be repeatedly applied over the part; and when you cannot employ them any more, then blisters should be had recourse to. You find it grateful to the patient to allow cold drinks, and there can be no objection to ices. There is intense heat and a great sensation of thirst, and the greatest comfort imaginable seems to arise from cold draughts. The best plan is to consult the patient's feelings; if he likes cold drinks let him have them, or if he like ices there is no reason why he should be debarred from them. You should follow the same rule as in inflammation of the surface—change these occasionally for warm drinks, and let the patient regulate the temperature. Of course it is necessary to keep the intestines in a free condition, and I should imagine it would be better to do this by clysters than by any other means. The stomach should be left as quiet as possible, and therefore I would trust this part of the treatment entirely to injections. With regard to the exhibition of mercury in these cases, I hardly know whether it is necessary or not, or whether it would be injurious or not. I have occasionally administered it where I was afraid that death would take place, without seeing the stomach irritated by it; but generally, if you remove the cause, which is something acrid, and have recourse to bleeding—if you give the patient cold drinks, and keep the bowels freely open—the inflammation of the stomach is in general disposed to subside.

Conjoined with other Diseases.—Inflammation of the stomach is very common in many acute diseases. It frequently occurs in erysipelas, and is sometimes evanescent—will go away, if you keep the patient low, without any treatment; but occasionally it requires local treatment. In fevers you must look out for gastritis: in the continued fever of this country, properly so called, and many other acute affections, this disease is very likely to spring up; and, therefore, in these affections you should always examine the state of the abdomen from time to time.

CHRONIC GASTRITIS.

Symptoms.—Gastritis is much more frequently a chronic than an acute affection. When it exists in a chronic form, the symptoms are much the same as when it is acute, only they are less intense. There

is a great sense of heat within the stomach, rising from the œsophagus into the pharynx; great thirst, tenderness of the part on pressure, loss of appetite, nausea, and frequent vomiting. The tongue is *generally* red somewhere—either at the tip, the sides, or all over; but you may have inflammation of the stomach, more or less violent, without redness of the tongue. You must not depend on the tongue alone. You generally see redness of the tongue, but you are not to say that the other symptoms do not shew gastritis because the tongue is absolutely white, or not much affected. In these chronic cases there are generally dyspeptic symptoms—such as a great flatulence, great acidity, and a sense of sinking at the pit of the stomach. The latter is a very common symptom, and, to remove it, people generally take wine and brandy, and make things worse. The want of attending properly to this point occasions very absurd treatment. I have seen persons in this affection have draughts of æther and ammonia, and things of that description; all of which may be grateful for a time, but frequently patients themselves say it produces great uneasiness. It is always right, when you are treating dyspepsia, to ascertain whether there is an inflammatory state of the stomach; for that organ may be in a condition requiring stimuli of all kinds, or on the other hand requiring the application of leeches, and making all stimuli and effervescing draughts exceedingly improper. Many persons labouring under this affection clearly have gastritis, for there is great pain on pressure; and because they feel a sinking sensation they drink wine, brandy, and eat meat, and I have seen them get completely well by changing their diet, without taking any medicine whatever, and in other cases by applying leeches.

A slight degree of tenderness not sufficient to require Leeches.—A very slight degree, however, of tenderness at the epigastrium, is not sufficient to make it necessary to apply leeches, or to lower the patient. You always find that when an individual is subject to violent fits of pain of the stomach, (gastrodynia,) or subject to occasional attacks, there is tenderness merely from the part being stretched. If you have spasms in the calf of the leg, you find the next day that the part is sore, merely from the muscular fibre having been stretched; and if you do nothing to make it worse, it will go away. There is no occasion to apply leeches simply because the epigastrium is tender. There has been for a certain time an attack of spasm, which has left a little tenderness of the stomach, and you will find it best yield to stimuli, just as a slight degree of inflammation of the eye is more easily dispersed by washing it

with brandy and water than by any other means. But if there be much tenderness on pressure and heat up the throat, then stimulating remedies would be improper.

Heat of the Epigastrium generally arises from Acidity of the Stomach.—It is also to be remembered that a sensation of heat in this part generally arises from the quantity of acid in the stomach, and if you give alkaline substances you entirely remove it, but if you think it right you can apply leeches also. If, however, you give alkaline substances (magnesia and carbonate of soda), you will find that a much smaller number of leeches will destroy the acid. Frequently this is the result of an inflammatory state, and the best way to cure it is to employ leeches; but to prevent the acidity, from doing much harm, you should give antacid remedies, or if there be morbid irritability, such a medicine as prussic acid will be of great service; but of that I will speak hereafter.

Accompanies other Diseases.—Chronic gastritis is an accompaniment of many other diseases, just as it frequently takes place after acute gastritis. You find it very common, in diseases of the heart, for persons to have more or less gastritis, which, if it arise to any amount, aggravates all the symptoms. You find tenderness on pressure, and this, perhaps, over all the parts; and you find, that some time before, the patient has had disease of the heart. So again, in phthisis it is by no means uncommon for a person to have more or less gastritic affection. In various chronic diseases this will come on from time to time, and requires to be remedied, or the symptoms of the original disease will be increased. It is well to ascertain the state of the abdomen from time to time, when patients are labouring under chronic affections, the same as when they are suffering under acute.

Treatment.—As to the treatment of the disease, it is simple enough. You should avoid stimuli, apply leeches from time to time, keep the bowels open, and remedy acidity.

ULCERATION.

Gives rise to no particular Symptoms.—When this inflammation has existed any time, it may perhaps ulcerate the stomach: such an occurrence is by no means uncommon. I know of no symptom indicative of ulceration of the stomach, and have frequently met with it by surprise. I have known that the patient has had chronic gastritis, but there was no symptom that would lead you to suppose that, in addition to that, there was ulceration. The symptoms are the same in both cases—tenderness, thirst, a sensation of heat there; of course dyspepsia, and perhaps

emaciation. Sometimes you will find pain at one particular part of the stomach, but then you may have that without any ulceration at all. There is no certain diagnosis: you may fancy it to be the case, but your conjecture may be wrong, and you may find nothing but chronic inflammation.

RUPTURE.

Symptoms.—If, however, the ulceration proceed to an aperture, then there generally occurs suddenly a fresh set of symptoms. There is sudden pain in the epigastrium—dreadful pain there; and in a case which I saw, there was also intense coldness, so that the patient held a glass of boiling water to the part without feeling it warm—without being at all annoyed by it; and he also drank water so hot, that I could not have put it to my mouth. You will find when I come to speak of dyspepsia, that affections of the stomach are frequently attended by a want of power to generate heat.

Generally succeeded by Peritonitis.—This pain, after it has existed for a certain time, is generally followed by peritonitis. You will find a paper on this subject by Mr. Travers, in the 8th volume of the *Médec. Chirurg. Transactions*, in which he states that he considers the diagnosis in a case of this description, or perforation of the intestines, would be sudden pain in one part of the abdomen; in the case of the stomach, at the epigastrium, radiating from the part; and he considers the pain would never cease. In a patient of mine where there was an aperture of the stomach, the symptoms were these:—I had never seen her before, but she was said to have been long dyspeptic, and she was tall and very spare. One day after dinner she was seized with a sudden pain in the stomach, and it was impossible for me to tell whether it was more than a spasmodic pain; for it was not aggravated by pressure. I gave her laudanum, of which she took 60 drops, and finding no relief, she took more, and so she went on till, in a few hours, she had taken 300 drops, and after that the pain ceased; and therefore it is not correct to say that the pain never ceases. I afterwards found some cases published in France, and also one by Dr. Carmichael Smyth, in which the pain went away, and therefore you are not to be sure that the stomach and intestines are not ruptured, because the pain ceases. After twelve or eighteen hours my patient again had pain enough, for the whole of the peritonæum became inflamed together, which could not be removed, and she died.

From the particular circumstance of the suddenness of the pain, the great prostration of strength, the smallness of the pulse, and the sinking of the patient, you may

imagine that the stomach or intestines have been ruptured, and you are not to imagine it the less because after a time the pain goes off. If the patient live long enough, peritonitis occurs, and various symptoms take place, rendering the case clear enough. You see that from rupture of the alimentary canal, peritonitis has taken place, but peritonitis that cannot be remedied, because there is a local disease keeping it up.

May occur without any sudden symptoms.—I believe I mentioned before that these perforations sometimes take place without any sudden symptoms; that, occasionally, slow peritonitis occurs, which gradually leads to ulceration.

Treatment.—In these cases of rupture, I should recommend the free exhibition of opium, and when inflammation comes on, the application of leeches, which will lessen the suffering, although you can do no further good.

Morbid Appearances.—If the destroyed portion of the stomach owe its condition to an ulcer produced by the gastric juice, you will not find the edges so smooth as in cases of simple ulceration, because the gastric juice does not of course act so very locally, but the parts all around suffer, and become soft. I believe that where the stomach has been injured after death, simply from the gastric juice, there is a softened state of the parts immediately around. You will recollect that the latter circumstance occurs particularly at the splenic end of the stomach, while common ulcers take place anywhere, and a patient previously in good health speedily perishes.

Ulceration not always productive of serious mischief.—You of course are aware that occasionally, notwithstanding the stomach is ulcerated, yet no serious mischief arises, because nature produces adhesions around the stomach, and glues it to the liver, the peritonæum, or the omentum, so that although the stomach is perforated, no aperture exists. Of course there is injury from the ulceration, but there is none from the perforation.

Pus.—Pus is actually found within the coats of the stomach, and sometimes it has been seen diffused throughout the whole of the stomach. Between the coats there has been one sheet of pus bounded by the peritonæum on one side, and probably the mucous membrane on the other, the muscular coat having been destroyed. But sometimes it has been found between the muscular coat and the mucous membrane, and the muscular coat and the peritonæum. Sometimes one small abscess is formed, and a collection of pus takes place in one particular spot. Pus has been found, it is said, on the inner surface of the stomach, but when you recollect that this part is naturally covered

by mucus, and sometimes this is secreted in a great quantity, one hardly knows whether there is really an alteration in the secretion. Still there is no reason why the stomach should not form pus on the inner surface, and no doubt it does exactly like other membranes, especially as it has occasionally been found on the external surface.

Fibrin.—It is a very rare thing to find fibrin effused upon the inner surface of the stomach, yet there is not a mucous membrane but what may form fibrin under violent inflammation. You will find it stated in authors that occasionally a false membrane, as it has been called, has been noticed on the inner surface of the stomach, but I believe this most frequently occurs in children. It is before puberty rather than after it that fibrin is formed in the œsophagus. If you find a false membrane in the œsophagus, it generally terminates in the cardia: so rare is it for fibrin to be formed within the stomach, that even if the œsophagus has produced it, the false membrane has generally been seen to end at the cardia. A layer of fibrin sometimes occurs in the throat, but it has not often been seen to extend lower than the upper organs.

MEDICINE — ITS PRIVILEGES, PURPOSES, AND PROSPECTS—

A Fragment from a Valedictory Lecture

TO THE STUDENTS OF THE UNIVERSITY OF
GLASGOW.

Preceded by a short

*Letter to the Hearers thereof, and to the Medical
Aspirants or Graduates of the said University
generally.*

Piccadilly, July 8, 1833.

GENTLEMEN,

IN obedience to your too often disregarded wish, that you might be able to refer to a few sentences, such as I am in the habit of addressing to you in concluding a long winter course, I now present to you a fragment of the last. I find nothing in it to abate, to alter, or to paraphrase. Two months are passed since we met, and much that concerns your interests and privileges (interests which I maintain, because I assisted to impart the privileges) has been transacting in this leviathan of cities. Of course you did not expect me, a prejudiced and trammelled Englishman, to be the Hannibal of your

descent and the leader of your march, exhorting you not to halt,

“donec Pæno milite portas
Frangimus, et media vexillum pono Suburâ.”

Yet, though neither authorised, nor inclined, to take an active part in this expedition, I seem authorised to be, and would fain be, your counsellor; and when you shall have come down from your hills, with your diplomas on the points of your lances, (having compelled Apothecaries' Hall, with all its mortars, to capitulate,) I so entirely approve of the stand you have made, that if you are in need of bard to sing your victory, and weave the epic of a new *Dispensary*, by the manes of Garth I will help you!

But suffer me to admonish you, gentlemen, that when you shall have made your election, and we shall have hailed your subsequent appearance in these parts, you will be expected to adhere strictly to the purpose you announced, and will be most decidedly and effectually discountenanced by all that is respectable among us, if you do otherwise. We must have no equivocal position. You come to be general Practitioners, or in the old phrase, Apothecaries; do not, therefore, let us see you, after you shall have abjured or deposed the doctorate, studious to affix a small brazen parallelogram over an otherwise unsuspected bell, lurking behind the lintel like a primrose under a hedge, with “DR. M'ANYBODY” engraved thereon, and in suspicious proximity with a shop-window exhibiting the prismatic colours: in short, do not attempt to receive the fee with the left hand, and dispense the remedy with the right; for we would not have, we will not have, the academical and scholar-like title of *Doctor of Medicine* mixed up with any thing *here* but literature or science. Being, therefore, as you are, good and very respectable *mediciniers*, take your position, and abide by it; and, if you do so, why, then, in the language of our own venerable College, that Warwick-Lane of old, to which the whole profession owes every thing it enjoys of consideration and importance in British estimation, “*precor vobis omnia fausta*,” and remain, &c. &c.

CHARLES BADHAM.

P.S. Since writing the above, I regret to hear that no immediate decision as to the claim of the Scotch graduates

to be English apothecaries, if it so please them, is to take place. *N'importe*: the day will come, and not tarry. The examination of our graduates at all, by a Society who become such by apprenticeships and instalments, is doubtless highly flattering to us, and to the Moures and Gregorys, our predecessors! They tell me that these respectable Galenists insist upon your knowing the colour, shape, texture, price, and idiosyncrasy, of all the crude vegetable productions from which the various drab-coloured powders of their shops are obtained. You are not collectors of simples, nor drug merchants upon 'Change; but pray learn them. I am glad, however, that they don't examine us. I think I know some Doctors, whom the world would be sorry to lose, that would make about as good a figure before the cabinets of the Hall, as would the Archbishop of Canterbury, or the Speaker of the House of Commons. The Apothecaries have improved medical education, quotha! no, no; they have neither improved medicine nor medical education. Medicine, like Thames water on a long voyage, is purging and depurating itself; and medical education has become better by the accession of ampler means of instruction, by the decay of public prejudices, and by the requisitions of a state of society, become more exacting, and compelling or inviting to more prolonged and effective studies. These, and not the Apothecaries' Bill, are the satisfactory reasons for the existence of a more intelligent class of practitioners than formerly. Now when a confederation, for whom such large claim as this is made, by not over-judicious friends, may, as it seems reasonable to suppose, have coveted authority for its own sake—for where one motive is adequate, we never look for two—and when very many of the individuals composing that body necessarily derive profit by the existence of legislative acts in their favour—where, I inquire, even had all that advantage to the public been derived which is pretended—where lies the claim to obligation? “There's lime in this sack.”

But, gentlemen, recent events make it impossible for me to rest here. When sitting in my place in the College of Physicians a few days ago, at its *comitia majora*, I heard recited an address from this Society of Apothecaries, stating, *inter alia*, and almost as an

added merit, that they were in the familiar practice of rejecting the Scotch graduates! and when I read in the Medical Gazette of this day (July 6th), from some person who appears to quote from authority, that in the last twelve months this incorporation has thought it proper, or found it necessary, to reject one-third of our graduates applying to them for license—more, eight out of twenty—I should feel it disgraceful to be longer silent, and cannot hesitate to identify myself (to whom no undue partialities for Scotland are in any danger of being imputed) with the Scotch petitioners for a bill of rights. Nor can I be lightly surprised that my colleagues, the respectable and learned professors of the northern Universities, have permitted themselves to remain silent under so direct an imputation of either breach of trust, or incapacity. To my portion of the reproach I will not submit, and shall be too happy to afford to the public, or to its delegates in the House of Commons, means to judge of its fairness. In honour and good faith we are, I presume, not below the individual examiners whom the Apothecaries' Company may have delighted to honour: in capacity to judge, being all of us public teachers, we can scarcely be rated as second to them; or, is the gentleman in brown or blue—of course I allude to no individual—is the contingent examiner of the day, indeed a better judge, in his own single person, of a young man's proficiency in the three subjects of anatomy, chemistry, and medicine, than Dr. Jeffray, Dr. Thomson, and myself respectively, and each in our line?—for the rejection of any one of our graduates supposes no less. If it be so, I think we had better resign our chairs to an individual who is, in fact, an university in himself. “*Le parlement!*” said Louis to his minister, “*le parlement!—c'est moi.*”

Gentlemen, I take no credit for thus defending you, because, as it happens, I conceive my character to be now inseparable from your interest. I am not sorry that the affair has been mooted; it must go on. *Vestigia nulla retrorsum.* There can be no compromise. I recommend you not to relax your exertions for a moment. My pen, if necessary, shall not be idle, but I would fain hope that there is *esprit de corps* enough

among my colleagues to join in some prompt and strong expression of opinion. To my fancy, "coming events" already "cast their shadows before."

May the Apothecaries' Act die with decent composure (we should wish an Euthanasia to our enemies); may it be embalmed in the opobalsams and medicated honeys of the Hall; may tears (of amber and other costly gums) be plenteously shed upon the bier, and the task of composing its Epitaph be confided to me.

C. B.

..... It is no ungrateful subject to me to speak the praises of medicine; to endeavour to warm the enthusiasm of my young hearers, by pointing out to them the privileges they acquire, and the rewards they may expect, as well as to inculcate on them the responsibilities they assume. I delight to tell them, that the more I have reflected on medicine, as a branch of knowledge, or have seen of it, as a profession, exercised by intelligent, cultivated, and benevolent men, the more I feel prepared to celebrate its pre-eminence, and to speak well both of it and of them. Of my professional brethren I have now known many; have known them in the fulness of philanthropic activity, as well as in the grateful repose of subsequent leisure; have seen their punctual carriages at the doors of those asylums of suffering which they so largely contribute to assuage, and have marked their bearing along those melancholy corridors!—the cheering kindness, the quick eye, the exercised mind, the dominant and paramount sense of duty, by which alone they permit themselves to be swayed, and through which alone they accomplish what they do accomplish. I have known them, too, *rude donati*, in the serene evening of a well-spent life, possessors of that soil of which they were not perhaps born the lords, watching over families to which they have not unfrequently imparted their own affluence of mental endowments, their own intensity of purpose, or their own felicity of manners. In, it may be, a somewhat humbler destiny than this, I have seen them, like Diocletian at Salona, interested in the precocity of their salads, or the success of their melon beds. I have conversed with my retired professional brethren in other countries, too, as well as in England; (Shakspeare's apothecary is a libel even

at Verona.) I have profited by an introduction to an eminent foreign surgeon, whom I have found bonneted, on a summer's evening, in his garden, bearing in his hand the *unstained* knife, the intelligible pruning hook of the horticulturist, in the midst of gay parterres, fountains of rather slender resources, and a whole mythology of gods and heroes in *lead*—that might have been advantageously dispensed with. An old physician, on his own lawn, with his Homer or his Plato in his hand, and in conversation with his gardener, is no ungraceful portraiture in real life. So much, then, for eventual or contingent rewards; results to which, as the poet says, all look, in all professions, and have a right to look! for men labour young, *senes ut in otia tuta recedant*. Such rewards it is certain, you will tell me, that all cannot have: true! but there are immediate and sure ones reserved for our profession only in its very exercise, rewards which address themselves equally to the heart and to the understanding.

For if we take up medicine in its intrinsic relation to the moral and intellectual happiness of its votary, is there any, let me ask, that so clearly *pays as it goes*? Medicine is, perhaps, after all, but a philosophical empiricism, rather than a regular and legitimate science; yet which of all the sciences does she not incessantly employ as her handmaid? Other professions, you see, are positively stationary, whilst ours is unerringly advancing with all progressing knowledge. Other professions appeal to, and owe their very existence to, authority; ours disclaims all such appeals, and acknowledges no dictator—the *Minerva medica* is to be propitiated only by sincere inquirers after truth. Other professions are builded up upon book learning: ours is really much more the result of observation, of experience, or, most of all, of reflection. Not but that we have books enough—rather too many; but the necessity of consulting them is, with us, most fortunately limited. Were the liberal professions to draw up this their heavy artillery for action, we should, in the category of number, make but an indifferent figure! for, allowing that even we may, by the agency of printing types, have been guilty of spoiling paper enough to cover the surface of a county, Law might extend her realms over a kingdom, and Theology over a hemi-

sphere—or have furnished paper sufficient for all the cartridges that have been exploded since the invention of gunpowder.

Cast your eye over the wide horizon of the medical sciences, and say if you do not find your profession, compared with other professions, even what a land under the most industrious husbandry, various in its productions and modes of tillage, is, compared with the steppes of Russia, or the unwrought wastes and wildernesses of the north! How very certainly, in our profession, all knowledge becomes power! Come, now!—are the elements of moral and metaphysical science inexpedient or inapplicable attainments, to those by whose acuteness mental infirmity is to be discerned, and by whose authority controlled? Can the experimental or mechanical philosophy be superfluous to the student who must make himself familiar, not only with the intrinsic play of mechanisms gifted with life, but with the influence of all external nature upon them? Is natural history, to say nothing of its boundless interest for its own sake, an indifferent acquisition to him who seeks new resources for his art, in all its kingdoms, or would illustrate what is obscure in his own structure and physiology, by what is familiar and demonstrable in the races of inferior beings? Is even an exact logic an useless instrument to the physician, who is ever balancing the most delicate and conflicting evidence, as he investigates the remote or immediate causes, the symptoms, pathology, or treatment of disease? No! he will lay all these sciences, and many more, under large contribution: he will *octroi* them all; and will draw new resources for his practice, or new inductions of reasoning, from the invasion of the soldier, the enterprise of the merchant, or the discoveries of the navigator. At so rich a banquet you may all assist! and assist, too, during the maturity and energy of existence.

Of the design and application of a profession, thus to be acquired and enlarged, can I give you an exaggerated account? Is there a nobler object than to assuage the throbbings of pain, and pacify the vigils of disease? It may be a flat thing (truth is often so) to say that health is the blessing *par excellence*, or to invoke her, with the epigrammatist, as “ eldest of the im-

mortals;” but sleep, appetite, activity, and all the best and blest emotions of our being, are they not inseparable from it? can the soldier fight, the statesman project, or the lover prosper, without it? and are we not the exclusive ministers and counsellors of this Hygeia, to whom all are glad to have recourse in their necessities?

And now on what terms or conditions is this ministry of our profession afforded to mankind? Why, in ten thousand instances, between every rising and setting sun, without money and without price does she extend her chalice of charity to all who thirst! Unlike to that profession which like the ancient oracle must be first propitiated with gifts, or is else silent, she requires no jar of oil, no “*vas pelamidum*,” she makes no stipulation for services to be done, but does them, and extends with equal assiduity her *ἡπεία ἀκεσμάτα*, her indefatigable Samaritanism, in the chamber of the dying prince, the tent of the wounded soldier, or the garret of the pallid artisan. Abandoned by, or, it may be, the victim of a sister profession (though I see no family likeness), she alone, or in company with another consolatrix (for religion and medicine may well take sweet counsel together), will be found assuaging the troubled spirit of the desponding prisoner. In moments of sudden and general danger and alarm, it is she that launches her ready life-boat before it hath been hailed from the wreck. Having no contingent objects of power, ambition, or station, to captivate and divert—it may even be to contaminate her offices, she is chargeable with none of the evils that unquestionably have been, and are, mingled with the good proposed or executed by other professions. Her only orthodoxy is, to be useful, and that, to Jew or Gentile, Mede or Elamite, Crete or Arabian. She seeks not, as from the dazzling prophet of Medina, to the gloomy Mahomet of the north, all have sought, and seek, an influence not legitimate, nor their own. She has scourged no schisms, chastised no heresies, conducted no martyrs to the stake! Medicine is, was, and ever will be, simply, undeviatingly, universally, and without the least obliquity of purpose, the benefactress of mankind, sending forth her useful missionaries, wherever ships can convey, colonies may invoke, or human sufferings invite them.

Gentlemen, the humblest of you may partake of these rights and immunities:

you are essentially a free people—ranks, orders, or distinctions, are small things with us! he that treats a fever is a physician, whether he be remunerated in cowries or in coin; our office, from the highest to the lowest, is essentially the same—knowledge with activity are all in all. I know not what you may think of it, but even the Esculapius of a rural district appears to me to stand in a very different position, as to the elements of self-esteem, from the equally well-known character who foment the discords of litigious farmers; applies the screw-press, the Vice of the law, to compel impossible rents out of harvests on which suns have not shone kindly; adjusts the machinery of the stocks on the articulations of the ragged mendicant; imposes a reluctant patronymic on the offspring of a stolen embrace; or inflicts hebdomadal penalties on village incontinence!

Upon the whole, then, you are not, I think, likely to repent, supposing that you were to choose a profession at all, that you have chosen medicine. They will tell you that it is overstocked, but so, it seems, is the whole planet; they will shew you that the eminent, the money-getting and flattering stations, are all pre-occupied—but on what tenure? *Οιη περ φυλλων γενεη, τοιηδε και ανδρων!* Once in ten or fifteen years, do we not see new names every where? Succession is your sure card; with doctors, as with patients, *ή μεν φνει, ή δ' αποληγει!*

STRUCTURE OF THE PLACENTA—

CONNEXION BETWEEN THE FŒTAL AND MATERNAL VESSELS.

To the Editor of the Medical Gazette.

SIR,

THE function of the placenta, and connexion between the fœtal and maternal vessels, is a subject which has lately occupied much attention; but so far from placing it in a clearer light, much of what has been written has rather tended to render it more obscure, and I can but congratulate myself, that instead of having to give up opinions which I fancied had been formed on sure data, and to consider as incorrect authorities which I had always been accustomed to look upon with the highest respect, I have now the satisfaction of knowing that the views which I have hitherto entertained

on this important subject are not only supported by a pretty numerous set of observations made since last January, but also strikingly confirmed by the valuable paper of Dr. H. Ley, and the not less interesting communication conjointly by Mr. Stanley and Mr. Mayo. I regret now not having requested the insertion of the accompanying observations on the structure, &c. of the placenta, in your valuable pages at an earlier period: they formed the materials of a lecture at St. Thomas's last October, and again in January of the present year. On the first occasion, I assured my pupils that these were my opinions, supported, it is true, by hitherto highly-esteemed authority; yet as other views had lately been adopted by men of merit in their profession, I could not advise them blindly to adopt one or the other, but leave it to time and opportunity to prove which was the most deserving of attention. In January, however, when I had again to discuss the subject to my class, my attention had been already directed to the openings which, in spite of assertions to the contrary, are so distinct in the uterine surface of the placenta; and I now declared my conviction that the facts, as stated by the Hunters, and the views which they had deduced therefrom, were correct.

To detect the presence of these foramina upon the uterine surface of the placenta, and to examine their form, number, situation, &c. minutely, it is neither necessary that the placenta should be injected, nor that any peculiar care should have been used to prevent its being compressed during its expulsion. I have carefully inspected some dozen placenta at the General Lying-in Hospital, both immediately when expelled, and also some hours after, and have found the above-mentioned foramina just as distinct whether the placenta had been subjected to pressure or not, whether they had been washed or not, &c. There is one fact, however, to be borne in mind, without a knowledge of which by far the greater number of foramina will escape our notice, or at least they will not be so easily distinguished, viz. that the placenta should be placed in such a position that the uterine surface shall present the same convex form which it does when adhering to the fundus uteri. If merely laid upon a flat surface, or suspended, as is evidently

the case with the beautiful engraving which forms part of the illustrations to Dr. R. Lee's paper on this subject in the *Philosophical Transactions*, the interlobular sulci are hidden, from the cotyledons being closely pressed against each other; and as by far the greater proportion of foramina are situated in these sulci, they will therefore be concealed from our view.

On looking into these interlobular foramina, we frequently distinguish the cavity branching off into subdivisions at a little distance from the surface, much in the same manner as the ramifications of the larger bronchial tubes. Openings upon the cotyledons appear to be much less numerous, at least they are by no means so easily distinguished as those in the interlobular sulci; but from being smaller, and having their edges thicker and apparently firmer, I should feel inclined to consider them as the *ci-devant* continuations of the uterine or decidual arteries, while, from their larger calibre and thin edges, most of the interlobular foramina may fairly be considered as venous, and in this supposition I am supported by the observations of Mr. Stanley and Mr. Mayo.

I will now proceed to describe the placenta in the manner which I believe to be correct, and in doing so, I must premise that my opinions have been formed chiefly, if not entirely, from the works which I read under the direction of a valued friend upon the continent; of these, Hunter, Lobstein, and Meckel, stand foremost. I have at different times examined a very considerable number of placentæ, and as yet have found no reason to doubt the accuracy of these physiologists. The reader will, I trust, excuse the short abrupt style of the following observations: they are little more than notes to form the groundwork of one or two lectures; and in some instances sentences have been translated or copied, wherever the description has particularly struck me.

The placenta (afterbirth) is formed essentially by the chorion and decidua; it is a flat, circular, or rather more or less oblong body, soft, but becoming firmer at its circumference; it is the most vascular part of the ovum, and by which this is connected most intimately with the uterus; its longest diameter is generally about eight, its shortest about six inches; its greatest thickness, viz.

where the umbilical cord is inserted, is about an inch, becoming gradually thinner towards the circumference. In primiparae it is usually situated at the superior and posterior part of the uterus, a little to the right, but we are unable to give any satisfactory reason for its being so frequently in this particular situation; its inner surface is smooth, being covered by the amnion, which at this point is somewhat thicker.

The placenta cannot be distinguished from other parts of the ovum till towards the end of the first month. In the second month it covers nearly half the surface of the ovum, gradually diminishing in its relative size as pregnancy advances, but increasing in thickness up to the full period of utero-gestation. It now forms a spongy vascular mass, its uterine surface divided unequally into irregular lobes, which have been termed cotyledons. The uterine surface of a full-grown placenta is covered with a pulpy membrane, very much resembling in its appearance and structure the decidua which covers the chorion, of which, in fact, it appears to be a continuation. This portion of decidua, which, from being interposed between the placenta and uterus, has been called "the placental decidua," is always found present at the end of pregnancy; it covers the lobes or cotyledons of the uterine surface of the placenta, descending into the sulci which run between them. In some parts it is thicker than in others, especially where it is connected with, or, in fact, becomes the decidua of the chorion or decidua reflexa. This membrane is pretty firmly attached to the vessels of the placenta, and cannot be separated from them without rupture, but by maceration its structure is more or less destroyed, so that the extremities of these vessels may easily be distinguished. The vessels which properly belong to it are very numerous, and like those of the decidua at other parts of the uterus, are furnished by the uterine vessels. Although it usually dips down into the sulci which separate the cotyledons of the placenta from each other, it not unfrequently passes from one to the other, forming, as it were, a bridge over what appears to be a clot of blood.

According to Lobstein, although this membrane appears to be a continuation of the decidua which covers the chorion, it nevertheless does not exist in the

earlier months. During the first months the placenta does not present a solid mass, with its uterine surface covered with projecting lobuli, as it does at the full term of gestation, but the vessels of which it is composed are loose and floating, as if it had been subjected to maceration. It has been supposed that this irregular lobulated appearance of the uterine surface of the placenta was the effect of its separation during labour; but this evidently is not the case, for Lobstein, having opened the uterus of a woman who had died in the fifth month of pregnancy, and separated the placenta with great care, found these lobular prominences, although not yet covered by the membrane which I have just been describing*. Wrisberg, professor of anatomy at Göttingen, seemed to be of opinion that this membrane, (the placental decidua) was distinct from the decidua reflexa, since with care the two membranes may be separated.

The existence of this membrane was noticed so long ago as by Dr. Burton, of York, in 1751, who observes (§ 18, p. 41) that "the side of the placenta next the womb is covered with a fine membranous continuation of the chorion." The human placenta, as in most viviparous animals, is composed of several portions, or lobuli, called cotyledons. The only difference is, that in the former they are united into a single mass, while in animals each is separately attached to the inner surface of the uterus. But although these cotyledons are united in the human species, we must not suppose them confounded together, or even that the vessels of the one have a direct communication with those of the other. We may prove this by repeating the experiments of Wrisberg, viz. by injecting

one of these lobuli, in which case we shall find that nothing will pass into the adjacent ones.

The structure of the placenta, it is well known, is vascular; in fact, we may say that it is almost entirely composed of blood-vessels, for as yet anatomists have not succeeded in satisfactorily demonstrating the presence of nerves or lymphatics in its structure.

On arriving at the fetal surface of the placenta, the umbilical vein and arteries divide into several great branches, which are situated beneath the amnion, and between the two layers of the chorion, to which they are intimately connected. These vessels supply the various lobuli of which the placenta is composed, so that each lobulus or cotyledon receives at least one of these branches; for although the umbilical cord consists of two arteries and one vein, this arrangement of the vessels does not continue into the body of the placenta, for there each artery is accompanied by its corresponding vein, a fact which may easily be demonstrated by examining the structure of a placenta which has been injected. When the vessels have reached the cotyledons, they are divided and subdivided *ad infinitum*. They are connected together by a fine cellular membrane, which may be very easily removed by maceration, and we shall then see the minute branches loose, and floating in the water.

If we inject water, melted wax, or quicksilver, into one of the umbilical arteries, it will return almost immediately by the other, on account of the free anastomosis which these vessels have with each other upon the fetal surface of the placenta; if, however, we close the artery, the injection will pass into the vein, but not until the whole placenta is injected; this, therefore, proves that there exists a free passage of blood from the arteries into the vein.

In the latter month the vessels of the placenta close here and there, especially at its external surface, and become solid fibres, which frequently contain more or less phosphate of lime. The description of the foramina on the uterine surface of the placenta has already been given. I will, therefore, pass at once to the relation between the placenta and uterus.

We know from daily experience that in labour, at the full term of pregnancy, the placenta is easily expelled from the

* Hence, in the earlier months of pregnancy, the placenta must be in direct contact with the uterus. At this period it is well known that the placenta is nothing more than a congeries of those tufts of arborescent vessels with which, during the first two months, the chorion is entirely covered. These vascular radicals, according to the authority of Lobstein, are venous; they unite to form the umbilical vein, and exist prior to the formation of the umbilical arteries. It seems more than probable that these venous radicles possess an absorbing power, and being in direct contact with the uterus during the early months of gestation, absorb that milky chylous fluid which is frequently observed at this time in the placental vessels, and which appears to be one of those numerous provisions for nourishing the fetus, which vary according to the period of gestation. After the fifth month, when the placental decidua is formed, the function of the placenta changes; the means of fetal nutrition are no longer what they were in the early months.

uterus; that on examining the surface which had been attached to the uterus, we find no laceration, and that a discharge of more or less blood takes place for some days after.

We also know that when the placenta becomes detached from the uterus during the progress of gestation, it is followed by a considerable hæmorrhage, which greatly endangers the life of the mother and child, more especially that of the mother. These facts prove that there is a circulation of uterine vessels in the placenta, which is destroyed when it is separated from the uterus. The question, therefore, is, how this circulation is carried on, and what is its relation to that of the fœtus? Different opinions have been entertained by physiologists upon this subject: some have asserted that there is a direct communication, or anastomosis, between the uterine vessels and those of the fœtus; in proof of which, the fœtus is said to have been drained of its blood in cases where the mother had died from hæmorrhage; and, indeed, the fact of hæmorrhage always following total or partial detachment of the placenta, has been supposed to confirm this view. The experiments of modern physiologists, however, completely controvert these arguments. Wrisberg found in the case of a woman in the seventh month of pregnancy, who had died from hæmorrhage, that the heart and blood-vessels of the fœtus were filled with blood, while those of the mother were empty. He examined several cows, &c. big with young, which had been killed by a wound through the heart, and *never* found that the blood-vessels of the fœtus were deprived of blood.

Ruysch, Monro, Haller, Wrisberg, Meckel, &c. have never succeeded in making injections pass from the uterine into the fœtal vessels. No anatomist has injected so many gravid uteri as the late Dr. William Hunter, but he was never once able to fill the fœtal vessels from those of the mother. Lobstein has tried repeatedly, and with the same result.

According to the observations of John and William Hunter, the placenta consists of a maternal and fœtal part. Besides the large sinuses which are continued into the placenta from those of the uterus, the maternal part comprehends those arterial vessels which are distributed upon the membrane which lines

the uterine surface of the placenta; the fœtal part comprehends that collection or mass of vessels which, properly speaking, constitutes the placenta.

Although the various observations, anatomical injections, &c. shew that to a certain degree there is a communication between the uterus and placenta, inasmuch as the blood of the former may be received into the sinuses and intestines of the latter, still we possess no proof that the blood can pass from these sinuses into the umbilical vessels; on the contrary, every thing serves to convince us that the circulation of the fœtus is quite independent of that of the mother. Dr. William Hunter has repeatedly had occasion to remark that two differently coloured fluids injected into the uterine and umbilical vessels, undergo no admixture with each other. This has been also confirmed by Mr. J. Hunter, in his "Observations on certain parts of the Animal Economy," where he says, "the substance of the placenta now filled with injection, *had nothing of the vascular appearance, nor that of extravasation*, but had a regularity in its form which shewed it to be a natural cellular structure fitted to be a reservoir for blood."

The maternal part of the placenta, therefore, consists only of the uterine vessels which convey their contents into the parenchyma of the placenta: this may be seen in every placenta which has been expelled from the uterus at the full term of pregnancy.

In this state the placenta presents the appearance of a spongy mass gorged with blood, which may be removed by washing or maceration; and if we inject a placenta thus prepared, the injection will readily pass from the umbilical arteries into the umbilical vein, but not one drop into its parenchyma. It is evident, therefore, that the blood which had filled the intervals between the vessels, and which had been removed by washing and maceration, could not have belonged to the fœtus, but must have come from the mother, for if any of the vessels had been ruptured, the injection would not have succeeded.

The manner in which the spongy parenchyma of the placenta is supplied with blood from the mother, I cannot do better than describe in Mr. John Hunter's own words. "The arteries of the uterus which are not immediately employed in conveying nourishment to

it, go on towards the placenta, and proceeding obliquely between it and the uterus, pass through the decidua without ramifying, just before they enter the placenta; making two or three close spiral turns upon themselves, *they open at once into its spongy substance* without any diminution of size, and without passing beyond the surface, as above described. The intention of these spiral turns would appear to be that of diminishing the force of the circulation as it approaches the spongy substance of the placenta, and is a structure which must lessen the quick motion of the blood in a part where a quick motion of this fluid was not wanted: the size of these curling arteries at this termination is about that of a crow's quill."

In this manner the umbilical vessels of the fœtus are always, as it were, bathed in blood; there is the same relation between these vessels and the blood of the placental sinuses*, as between the internal carotid or sixth pair of nerves, and the blood of the cavernous sinus, or still more strikingly between the branches of the pulmonary artery and the air which fills the bronchial cells.

I have purposely omitted any observations upon the formation and development of the maternal and fœtal membranes, and also upon the nutrition of the fœtus, perhaps one of the most interesting and beautiful subjects in physiology, but I have occupied so much of your valuable pages that I will proceed no further for the present.—I am, sir,

Your obedient servant,

EDWARD RIGBY.

44, Parliament-Street.

RUPTURE OF THE AORTA INTO THE PERICARDIUM.

To the Editor of the Medical Gazette.

Bristol, July 8, 1838.

SIR,

As rupture of the aorta into the pericar-

* The vessels which convey the maternal blood through the placenta have been differently named by different anatomists; but I am inclined to think that these vessels may successively come under the denomination of cells, sinuses, or veins, according to the point at which they are examined. In this respect the placenta appears to possess a more perfect structure than that of the lungs, inasmuch as the maternal blood has not to return by the same passages through which it entered, as is the case with the air in the lungs, but is carried off by a different set of vessels.

dium is of rare occurrence, permit me to state the following case.

Yours respectfully,

EDWARD HUMPAGE.

A man, aged 38, by occupation a sawyer, had complained of occasional pain under the sternum during the last three weeks of his life, but the uneasiness was not sufficient to prevent him from following his work. After eating a hearty dinner, and drinking freely of beer, he was seized with slight convulsion, which, in a few minutes, terminated in a fatal syncope.

We examined the body twenty hours after death. The cellular membrane was loaded with fat, and the muscular parietes of the thorax and abdomen were finely developed, owing, doubtless, to the nature of his employ. On raising the sternum, the lungs presented a very healthy appearance: there were some few adhesions between the pleura, which, from their firmness, appeared to be not of recent date.

The pericardium presented a distended appearance, and, on puncturing it, a quantity of bloody serum flowed, under which was a layer of coagulum completely covering the heart; the fluid altogether would perhaps have weighed twelve ounces. This and the coagulum being removed, the pericardium, as well as the substance of the heart, were found quite free from disease; so were also the auriculo-ventricular and semilunar valves.

Where the ascending joins the transverse part of the arch of the aorta, there was a small irregular opening looking towards the vertebral column, about the size of a split pea, through which the blood had escaped.

The coats of the vessel were very thin just in the vicinity of the opening, and appeared to have been eroded by a species of ulceration. In the neighbourhood of the opening, the arterial tunics were fully three or four times their natural thickness, alternating with points of extreme tenuity: this diseased state of the vessel extended through a space about the size of half a crown.

The aorta was certainly dilated at the diseased portion, but no regular sac was formed, nor any thing like a laminated coagulum.

Was the disease one of acute inflammation, ending in ulceration? That it was an acute disease of the artery, I think, must be allowed, since the man

had not complained more than three weeks, nor did we see the usual indications of long-continued disease in the morbid alterations of the surrounding parts.

Not having seen the man during life, I am unable to give a perfect history of the case, otherwise it would have been an interesting subject of inquiry how far his occupation tended to the production of the disease. This is certain, that he worked on the day previous to his death, and only complained of occasional cutting pain under the sternum.

The viscera of the abdomen were perfectly healthy, and with the exception of the cardiac glands, which were enlarged and contained melanotic matter, no other deviation from a healthy structure could be detected.

NEW FORMS OF SPLINTS FOR THE ARM AND FORE-ARM.

To the Editor of the Medical Gazette.

SIR,
WHERE the science of mechanics can be

brought in aid of that of surgery, it must be very desirable to the humane practitioner, as in many cases, when applied with skill and ability, it will tend much to alleviate the sufferings of the patient, and redound greatly to the credit of the surgeon.

For some years past I have devoted much time, attention, and expense, to the subject of fractures and dislocations of various bones, and the result has been the construction of certain splints and other machinery, which, as far as I know, are quite new, and which, in my extensive practice in this manufacturing district, have answered the end required to my most perfect satisfaction. They have been exhibited in some of the lecture-rooms of the metropolis, and highly approved of by several hospital surgeons of the first character.

The accompanying drawings of splints for the arm and fore-arm are specimens of some of these, and which shall be followed up by others, when I can obtain them from the artist. You will oblige me, therefore, and I hope also the profession at large, by making them

FIG. 1.

FIG. 3.

FIG. 4.

known to the public through the medium of your highly-valuable journal.

I have, &c.

JOHN GRANTHAM.

Crayford, Kent, June 27, 1833.

FIG. 1

Represents an apparatus for fractures of the humerus: *a* is a splint for oblique fracture in an adult, with a screw to extend or shorten it; it is applied with a concave splint (*b*, *c*, or *d*.) to the under or ulnar side of the os brachii; *a* is secured by means of a strap applied round the opposite axilla; the splints *b*, *c*, *d*, and *e*, may be secured to *a*, with broad tape. The splints *b*, *c*, and *d*, may be applied, without *a*, in transverse fractures, or those fractures of the humerus which occur in delicate subjects, where the muscular power is not great.

FIG. 2

Represents a pair of splints for fracture of the radius; *a* is so applied as to prevent pronation of the hand.

FIG. 3

Represents the application of the apparatus fig. 1.

FIG. 4

Represents the application of the apparatus fig. 2.

ON THE CONTAGIOUSNESS OF ERYSIPELAS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following brief statement of facts, which I have thrown together for the purpose of endeavouring to add to our knowledge on the above interesting and important subject, appear to you worthy of your valuable columns, it is much at your service for publication. I shall here merely remark, that instances so palpable of erysipelas being communicated from one person to another, and this too not in the contaminated atmosphere of a crowded hospital, but in the pure air of the country cottage, have not heretofore come under my observation; and as one fact is worth a thousand speculations, I trust

the subjoined histories need not the aid of any comments (even if I were disposed to enlarge upon them) to render them intelligible, if not satisfactory, to your readers. I would, however, take leave to direct attention to the circumstance, that the disease originated in a common way, viz. after a wound of the scalp, and therefore it may be said—*per se*; but that it afterwards attacked those who had no wounds or sores.

I beg to remain, sir,

Your obedient servant,

G. BURY.

Farnham, July 9, 1833.

CASE I.—*Erysipelas supervening on an Incised Wound of the Scalp, and thence spreading by contagion.*

In the middle of May last, William Parfitt, a healthy young man and agricultural labourer, received an incised wound of the scalp, from the axe of a fellow workman flying off its handle after the blow was struck with the tool. The wound was about three inches in length, on the left side of the occipital protuberance, and attended, I am led to believe, by severe symptoms of concussion. These were fortunately only of short duration. The assistance of a surgeon at Odiham was procured, as the accident occurred within two miles of that town. He applied adhesive plaster, and repeated this dressing three or four times.

At the expiration of ten days the man had so far recovered from the effects of the injury as to be enabled to walk to his home (a distance of five miles) at Crookham, the wound then being in a favourable state, and all symptoms of concussion absent. About a week after his return I was requested to see him, as I was passing by his house, and found him labouring under very considerable febrile excitement, and the wound in a sloughing condition. There was perfect absence of any signs of concussion or compression of the brain. Under the free administration of purgative and febrifuge medicines, and the use of chloride of lime and bread poultices, the wound became clean, and the febrile disturbance subsided in the course of a week. This gratifying amendment was, however, shortly interrupted by the supervention of erysipelas, which extended from the wound over the entire head and face, and some distance down the neck. The patient's

strength having been necessarily reduced by the previous antiphlogistic treatment, the disease assumed the asthenic character. Delirium, attended by low muttering, soon set in, and was rapidly succeeded by coma. Stimulants were with the greatest difficulty swallowed, and the case wore a most unpromising aspect.

Not to enter further into the particulars of the treatment, which were foreign to my present purpose, I will just state, that the progress of the erysipelatous inflammation was arrested by employing the lunar caustic in the mode recommended first by Mr. Higginbottom, and subsequently by Dr. Elliotson and others. The system was at the same time supported by the copious exhibition of wine, spirits, æther, ammonia, &c. &c. The patient's recovery was gradual, and he has now (contrary to my expectations at one time) regained his pristine strength.

CASE II.—Not more than a week from the period of the disease being at its height in the preceding case, the sister, Ann Parfitt, who had been most attentive in nursing her brother, was attacked, though slightly. The erysipelas faintly appeared between the scapulae, and the concomitant feverishness was so trivial as to be quickly subdued by medicine. The application of a cold lotion was the only local treatment here practised.

CASE III.—The father, who also had been a great deal with the first patient, was the next attacked, and while Case II. was going on. The erysipelas commenced in the axilla, and thence diffused itself over the whole side. I made two small incisions into the inflamed surface with the scalpel, from which some blood only escaped, and the tension, redness, and pain, were perceptibly diminished. The incisions were made on the second day, but even thus early delirium had come on, and it was speedily followed by coma. The poor fellow had been a hard drinker, and his constitution, originally most robust, had been manifestly shattered by the abuse of beer and spirits, by hard work, and also by several very severe injuries he had sustained in pugilistic contests. His age was 56, and despite of cordials and stimuli, he sunk on the fourth day from the beginning of the disease.

CASE IV.—Mary Parfitt, another sister, 26 years of age, was the next to sicken. She also had been constantly waiting on her father and brother. The face and some portion of the neck were occupied by the disease. Delirium began on the third day, but did not terminate in coma. This patient, however, required the prompt administration of nourishment and stimulants.

CASE V.—Daniel Parfitt, a brother, who had lately come home ill with low fever from Odiham, became the subject of erysipelas the following day after Mary was attacked, and his case was in all essential points similar to hers. The lunar caustic was locally employed in both, with most marked good effect; and the patients are now convalescent.

CASE VI.—David Parfitt, æt. 22, the only one remaining unaffected in the house, was at length not suffered to escape. After experiencing febrile symptoms of one week's duration, he became worse, and erysipelas was developed in the face on the 4th of the present month, ten days after Daniel was seized with it. The attack was milder than in either of the foregoing instances. A decided check to the advancement of the inflammation was produced by the caustic, applied as before.

Purgatives and antimonial preparations were liberally given in each individual case, and the inflamed parts kept wet with lotio plumbi.

The situation of the house in which these patients lived is healthy, and at the extremity of a small village. I had not seen erysipelas in the neighbourhood or parish, which is very extensive and populous, and of which my partner and myself have had the medical charge for four months, before I witnessed it in the person of William Parfitt, and I have every reason to believe that the disease was not any where near till then.

One person only, residing in another house in the village, has had the disease, and that was the aunt of the above persons. She was taken ill after No. 2, and had sat up two or three nights with No. 1, and had likewise been much with him by day. The case has, I understand, done well; but it did not fall under my own observation.

ON THE *MORDIXIM* OR CHOLERA OF JAVA AND MALABAR.

To the Editor of the Medical Gazette.

SIR,

I SEND you the following remarks on the *Mordixim* of Bontius (supposed to be the first author who noticed the cholera of the East), with a curious but brief account of the Portuguese in India between two and three centuries ago, which you may consider worth insertion in the Gazette.

An old history having fallen into my hands, written by Grimeston in the year 1612, I find that author, after describing the effects of the Monsoon, (a word, by the by, of which he seems quite ignorant,) to say,—“They that remaine at Goa fall into many Diseases by Reason of this Change, for they haue one sodaine Infirmittie called *Mordixin*, which comes vnto them with so great a Vomitting as they are readie to giue vp the Ghost: this Disease is common and mortall.” As an historian, he merely states the suddenness of attack, the vomiting, its fatality, the name it bore; that it was common; naturally to be expected at a certain season; in fact, endemic. Bontius, the Dutch physician, who wrote at Batavia in 1629, mentioned that the islanders of Java denominated it *Mordixim*, at which time the Hollanders had not finally settled in the island more than eleven years; for they fortified Batavia in 1618, six years after Grimeston had published his “*Historie*” in England. The Portuguese had occupied Goa on the Malabar coast since 1510, distant from Batavia *two thousand three hundred and forty-six* miles, a long and tedious navigation in those days; and I conclude, that as the disease was common in one place, and had broken out at such a distance in another—both settlements occupied by such implacable enemies—it must have been universally known by its ancient appellation from one end of India to the other.

I now have to give my explanation of the origin of *Mort de Chien*.

From 1595 to 1612, a period of seventeen years, India was first and successively visited by the Dutch, English, French, and Danish adventurers, all of whom, it may be imagined, occasionally experienced the mortal visitation amongst their land and sea forces. In their in-

tercourse with the Portuguese, who pronounce the *x* as *sh* in *Mor-de-xin*, they might, and perhaps did mistake it for a French phrase, and thus the adoption of a Gallican term, as a generic name, may be explained, without censuring Soumerat or any other writer for the transformation; although I cannot conceive why *la Fête des Morts* (All Souls'-day) should be better French than *la Mort de Chien*, alias *Morderin*.

The next passage, from its antiquity, is very interesting:—"The Flux is also contagious there, as the Plague is with us; continuall Fevers kill men often in three or foure Daies; the Portugals finde no better Remedie than to draw Blond. These Diseases kill many Portugals yearely, for they cate nothing which is of good Nourishment, and abandon themselves to glut their Lusts with lascivious Women. We may see the Experience in the King's Hospitall, which is a Retreat for Portugals onely, out of which there are carried every yeare foure or five hundred dead Persons. The Fox are very general amongst them, neither is it any Blemish to him that hath them; they haue the Remedie from China Roots, and although they bee much infected, yet no man dies them; no, although they haue had them three or four Times; but contrariwise they glorie in them, and hold this for a sweet Paine in Regard of others."

I may here observe, that until these few years back, the flux or dysentery has been always considered highly contagious in India: the "*continual fevers*" are the endemic bilious fevers, and it was only by free and copious bleeding that the violent pain of the head, gastric irritability, and visceral engorgement, could have been relieved. The non-mercurial treatment of the Portuguese-Gallico, (for, with them the French have all the honor of it,) must have succeeded well in such a country with vitiated constitutions. The China roots I presume to have been the *decoctum lusitanicum*, which was considered as a specific more than 200 years ago; and if the sarsaparilla was not then to be obtained in India, the *similar china* was in its composition held in as much esteem; and however such debauchees may have gloried in the disease, they had good reason to rejoice in their doctors, as they appear to have been ignorant of, or abstained

from "pushing the mercury," a practice in my young days in every form of the complaint, and fraught with evil.

I am, sir,

Your obedient servant,

MEDICUS CASTRENSIS.

Compton Gifford, Plymouth,
June 24, 1833.

REFORM OF THE COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

For many years past the cry has been, that the Royal College of Physicians of London requires reform. The complainants however have, for the most part, dealt in generalities, and, at any rate, have carefully refrained from investigating the question, "What is the actual measure of reform which the circumstances of the times require, which may be yielded without injury, and with which the Licentiates ought to be contented?" The time is arrived, sir, when this question should be discussed, and the following is an humble attempt to solve the problem.

Some persons have cut the gordian knot by stipulating for an *equality* among the members of the College. I know but of two objections to this scheme: first, that it is impracticable, even in *this* age of liberality; and, secondly, that if it were attainable, it would be mischievous. There must and ought to be *orders*; but the question is, whether a different division from that of Fellows and Licentiates might not be found both attainable and useful.

My plan is this:—1st, Let a new charter be issued, under which the College shall be divided into two orders—senior Fellows and junior Fellows. 2d, Let the senior Fellows consist of all the existing Fellows, with the addition of such of the Licentiates as have practised in London for twenty years with credit and reputation (the selection to be made in the first instance by the Secretary of State for the Home Department.) 3d, In future let all candidates for Collegiate honours, whether Graduates of an English, Scotch, or foreign University, be received in the first instance into the class of junior Fellows; and let it be understood henceforth, that

those who are unfit to be Fellows are equally unfit to be entrusted with the lives of his Majesty's subjects. 4th, Let a certain number of the junior Fellows be annually elected by the senior Fellows into their own class, no one to be eligible for the higher rank who has not been five years in actual practice as a junior Fellow.

More than this no Licentiate ought to ask: with less than this no Licentiate should be satisfied. The plan preserves to the existing race of Fellows all their present honours and dignities. It conciliates the Licentiates by abolishing a title which they justly view as the badge of inferiority, and in a few years it will thoroughly amalgamate them with that portion of their professional brethren whom they now unhappily look upon as their oppressors. The plan is of easy execution, and I sincerely trust that it will receive the candid consideration of those in the College to whom providence has given the ability, and the law the power, of doing unto others as they would that others should do unto them.—I am, sir,

Your very obedient humble servant,

A PETITIONING LICENTIATE.

London, July 13, 1833.

ANALYSES AND NOTICES OF BOOKS.

“L'auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Embryologie, ou Oologie humaine; contenant l'Histoire descriptive et iconographique de l'Œuf humain. Par M. A. J. M. Velpeau, Chirurgien de l'Hôpital de la Pitié, Agrégé à la Faculté de Médecine de Paris, &c. Accompagnée de quinze planches, par Chazal.

In our former notice of this work* we hastened to give the opinions of M. Velpeau on a point of structural anatomy which has recently been much controverted: it was gratifying to see how this acute and able author dealt with a question which has of late acquired so much importance—some of the ablest anatomists of Europe having taken it up with earnestness, and in several instances arriving at very opposite conclusions. The

candour of M. Velpeau is praiseworthy. He acts fully up to the principle which he states in his preface: he treats the living as boldly as he does the dead, and the most distinguished authorities (when they deserve it) as observers of little worth. “I have never thought,” says he, “that to contradict an author is to treat him ill: it is surely very possible to attack the opinions and works of men of the highest merit without falling short of the respect due to them, or even ceasing to admire them. I am aware that in France it is not yet greatly the custom so to do, and that in the eyes of many persons, to dispute a man's positions is to make a sort of declaration of war on him. But the interests of science ought to obtain the first consideration; and it is with this feeling that I am reckless about private prejudices.”

The contents of the *Embryologie* are exceedingly rich and valuable. We find them comprising every thing that is positively as well as conjecturally known regarding the embryo and its appendages, externally or independently considered. It is, it seems, the author's intention in a future work to treat of the development of each system, organ, or viscus involved in the pregnant state from the first weeks up to the period of birth. This corresponding portion of his labours he announces as his intended *Organogenesie*.

M. Velpeau gives a list of the obstacles which stand in the way of inquiries on embryology. Among them he mentions the utter ignorance which in almost every case exists as to the exact period of pregnancy—the impossibility of knowing the length of time that may have elapsed from the death of the fœtus to its expulsion—the difficulty of satisfying ourselves as to the amount of disorganization which affected the embryo or fœtus in utero before miscarriage took place—the uncertainty of result attending even the most careful anatomical manipulation—and the delusion of optical examinations. But what he dwells upon as peculiarly liable to disturb, and which has often disturbed, the results of attentive research, is the mistaking some minute object in the first instance, and thus carrying the error of the premises inevitably into the conclusion. The amnion, for example, is wanting, as often happens, and the observer takes the chorion in its place: it is readily conceived how much confusion may thus

* See page 435, *ante*.

arise. The chorion mistaken for the allantois, the decidua for the chorion, the lining membrane of the uterus for the decidua, all contribute to involve the result in a labyrinth of error. It is, by the way, with a sort of misprision of this kind that the author charges Dr. R. Lee, while he adopts with eagerness almost all that gentleman's other conclusions. Dr. Lee, he thinks, has mistaken the internal membrane of the fundus uteri for the uterine portion of the decidua; but it is a mistake, he says, which has been committed by numbers of observers, and there is not the slightest imputation attachable to any one for falling into it. Our author is very charitable; but to confess the truth, we strongly suspect he has himself mistaken Dr. Lee on the point. Some idea of the care required in treating of the more subtle membranes of the uterine organ, may be formed from the fact, that for the *decidua* of Hunter there are enumerated by M. Velpeau no less than fourteen several synonyms in use with different authors; and for the *reflexa*, nine.

The introductory portion of the work is occupied chiefly with a discussion of the claims of MM. Dutrochét and Brechét as original observers in embryology. Between the latter gentleman and M. Velpeau there seems to be a direct rivalry on the subject of uterine anatomy. Some years ago they carried on their researches in common; employed the same artist to delineate the same preparations to illustrate their respective views; and they have published their separate works about the same time, containing not only *fac simile* plates, but many *fac simile* statements. M. Velpeau gives an *exposé* of those points in which they seem to copy each other, and, of course, vindicates his own priority of claim by chronological reference to his publications. However interesting it may be to many people to investigate the respective rights of the parties, all that the public will, or ought to care for, is the fact of the coincidences in their separate works and the probability of the correctness of opinions in which two such able rivals have concurred. Another very important part of the introduction is that which sets forth the views of the German school touching almost all the controverted points of embryology; M. Velpeau gives us an able abstract from Burdach on the subject, which exhibits

at once, he says, the fairness of the author, and the danger of abandoning facts, in favour of analogies and flights of imagination in the physical sciences.

It would be impossible within the limits of the present notice to follow M. Velpeau through the execution of his work. He divides his subject simply into two sections: in the first he treats of the *annexes* of the fetus, and in the other of the fetus itself. The annexes embrace the membranes, the vesicles, and the placenta and cord. The membranes he reduces to three—the decidua, the chorion, and the amnion—of each of which he treats separately.

We have already intimated the opinions of M. Velpeau respecting the structure of the placenta: our readers may not be displeased now to have an account of his views regarding the

“Union of the placenta and the uterus.”—On this point physiologists have been much occupied. Northwyck, Astruc, Haller, Mery, Baudeloque, thought that the great venous canals of the uterus were continuous with those of the placenta. Warthon, Reuss, and a great many moderns, think that the point of the uterus in contact with the ovum in the beginning of pregnancy, becomes fungous, and that the fungosities which constitute the uterine placenta intermingle and coalesce with those of the chorion, so that there must be a laceration on the expulsion of the afterbirth. Even Professor Dubois advocates the latter opinion, holding, moreover, the milk-fever to be a true traumatic pyrexia.

“According to Stein, the lobes of the placenta are *impressed* into the uterus, the ramifications of its vessels being thus implanted into the great sinuses of the uterus, like the roots of a plant in the soil. Asdrubali supposes that the placenta adheres to the uterus as the succulent part of a peach to its kernel. Leroux compared it to the attachment of a leech to the skin. Others maintained that the union was like that of grafting on a tree—that it takes place through an accidental cellular tissue—through particular vessels, &c. What I have already said on the structure of the placenta is sufficient, I should think, to prove that none of those hypotheses are exactly correct. I should say with Me. Boivin, that in numbers of women who have died in the pregnant state,

the sole connexion that seemed to unite the placenta and the uterus was the membrane covering and uniting the lobes of the former organ.

"I have observed, besides, that the adhesion of the ovum is uniform throughout, and that it can be destroyed with the handle of the scalpel without any difficulty, or without breaking any thing except certain mucous flakes (tractus) similar to those existing between the amnion and chorion, or between the false membrane in croup, and the tissue that gives it origin. The great source of error has been that authors have had few opportunities of observing the ovum in its natural situation, and that where women have died a few days after delivery, the internal surface of the uterus has appeared swollen and fungous in the part corresponding to the adhesion of the placenta.

"We should just recollect two circumstances. The internal membrane of the uterus, which is so well developed, and easy to be dissected in most pregnant women, speedily becomes soft and disorganized after death consequent on abortion or delivery, so that it is very liable to mislead. If the ovum be not entire in the uterus, and the organ has contracted in some degree, there is an appearance of laceration where the placenta was attached, which would induce a person to infer an intimate union between the bodies in their natural condition. When the parts are examined *in situ*, and the pregnancy has exceeded the fifth month, it is easy to shew that the uterine sinuses are prolonged by large and oblique openings even to the surface of the placenta, or perhaps the whole of the ovum; but these openings, furnished, as it were, with valves, or fine membranous veils, (probably consisting of the mucous tunic itself) have no correspondence with any vascular orifice either in the decidua or the placenta. In this particular there is still room for many new researches."

In the second section M. Velpeau treats of the curious subject of the earliest appearance of the embryo, its primitive form, and of the successive developments of its different parts. He is more brief on the latter head than he would otherwise be, in consequence of the contemplated treatise already alluded to.

The plates are beyond all praise, but must be seen and thoroughly examined to be appreciated as they deserve.

Illustrations of Vegetable Physiology, &c. BY JAMES MAIN, A.L.S. &c.

THE object of the author of this neat little volume is to present a plain and concise view of the various structure, functions, and properties of plants, and to do this in a popular rather than in a strictly scientific form. We think he has succeeded in his design: he has given us an excellent compendium of the many important discoveries which have of late been made in this branch of science, and has interspersed a good deal of original observation, derived from a lengthened practical experience. The book is embellished with a profusion of well-executed wood-cuts.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL DEGREES IN LONDON.

It has long been acknowledged that this metropolis possesses all the requisites for a great university: there is no branch of science or art that does not find in it able cultivators and accomplished teachers; and, which is most to our purpose, as a school of medicine, in despite of the absence of certain externals, it has long enjoyed a high degree of celebrity. One thing alone it has wanted to put it on the footing of other European universities—a bond of union combining its several parts, and a recognized head to distribute its rewards—to wield the government of the whole.

Some there are, whose minds have never been much directed to the subject, who fancy that an especial structure, a distinct "local habitation" as well as a "name," is essential to this end—that there must be some handsome range of buildings, as at Berlin, Edinburgh, or Dublin, devoted to the purpose; and for this reason can scarcely comprehend that a *real* university might exist here

without some tangible, visible, and distinct pile worthy the magnitude of the metropolis,—the erection of which would be an undertaking of vast risk and expense, well calculated to make even the most ardent pause. Those persons are very imperfectly acquainted with the constitution of such a place. Let them look to a neighbouring kingdom possessing one of the oldest institutions of the kind in Europe—that of Paris. Yet where is the University of Paris as a pile? Its head is commonly observed at the Sorbonne, and has often been elsewhere; but its component and integral parts are well ascertained, though they are diffused over a large space, situated in some instances many miles apart from each other—consisting, in short, of a certain number of distinct colleges or recognized schools, the students of which, after having complied with certain regulations, are eventually certified by the caput. The same is true of other well-known universities of the continent. But why go abroad for an illustration which we may have at home? Every one knows, or ought to remember, that our venerable establishments of Oxford and Cambridge consist of nought else than certain united schools subject to the rule and governance of an appointed head. The several buildings belonging to the schools are more nearly situated with regard to each other than those of Paris, but in little more than this consists the only difference.

What, then, is wanting to render London essentially an university, but to incorporate the several distinguished schools existing within it, thus rendering them virtually so many colleges, and to vest in a particular body the government of the whole? This would be reform on a grand scale. The particular body should not be part or parcel of any of the subordinate establishments; no teachers from the different schools, much less those of a particular school, should have

any part in the control of the general institution.

But perhaps it may be thought that this plan—though there may be nothing actually unreasonable in it—is too extensive, and that there are certain conflicting interests to be reconciled before it could be rendered in any degree practicable. The ancient and aristocratic establishments in the provinces have, it is known, a veto, which they can use with powerful effect with regard to any arrangement threatening to interfere, as this plan assuredly would, with much that is unquestionably valuable in their present forms and constitutions. Be it so. Yet to the extent that our desires go to aid in a reform in this matter—we mean in order to render London so much of an university as to be competent to confer *degrees in medicine*—the thing is very far from chimerical. If, indeed,—in the event of such a project being set about in earnest,—Oxford and Cambridge, with their acknowledged deficiency in the means of bestowing *medical* education, should interfere with a prohibitory design, then will it be demonstrated how far these institutions are mischievous monopolies, and how far the spirit of mammon has infected their councils: then will they be enabled to experience whether there is more terror in the censures of the judicious than in the rage of the destructives.

Each of the other capitals of the United Kingdom has its university—with, of course, all those powers which the name of an University implies; and why, may it be asked, is London, the capital of the empire, and the greatest and richest city in the world, without one? The question has frequently been put, and its force of late so well understood, that on the strength of it, it has been attempted to palm upon the public the speculation of a joint-stock company, assuming in the boldest manner the name; but enough of this. The

reason, if it should be attempted to be assigned, why London has hitherto been destitute of an establishment capable of conferring degrees, might be variously stated; it would seem to have been owing to a combination of circumstances—the proximity of Oxford and Cambridge—the accidental circumstance of having no structure originally founded for such a purpose—the force of precedent, which is so characteristically distinctive of all the institutions of this country—and perhaps the fond partiality of those who have the power to manage it otherwise, for their own favoured places of education. Now let all these circumstances have their due weight—let them, and we will offer them no opposition, still prevent the erection of a rival University in the metropolis, one affecting the same range and extent of powers as the sister establishments in the provinces; yet we will say, that when the public good—nay, absolute necessity—imperiously requires that at least, so far as *medical* degrees are concerned, there should be a competent authority vested in some institution of the metropolis, in order that those who are here educated may not have to travel elsewhere for a certificate of their qualifications—and the more so, as the provincial establishments are so utterly defective in the medical department of education—we say, that in this case it is impossible that any one should reasonably maintain that the least weight should be attached to the above-mentioned combination of circumstances.

We last week stated our views as to the propriety of entrusting to the College of Physicians the power of conferring medical degrees. We argued that as the contemporary institutions, the College of Surgeons, by conferring their diploma, constituted surgeons, and the Society of Apothecaries had the power of sending forth general practitioners—there was no reason why the College of Physicians should remain in an anomalous

condition, incompetent to constitute their diplomatist an M.D. We shall not pursue the subject farther at present, but merely add, that of course before such an important privilege should be confided to this institution, certain changes will be requisite—means must be taken to conciliate more or less the large body of individuals who are earnest, and, we believe, not unreasonable, in the expression of their dissatisfaction: ample inquiry, in short, must be instituted into the present condition of the College, with a view to certain salutary modifications. By such a step—and such only—we mean by the purification of the source whence it is intended that honours shall flow—the College will acquire that popularity and influence which it at present confessedly wants; while power conferred (if we can conceive the possibility of such an occurrence in these times, so distinguished by the jealousy entertained of all close corporations) without previous investigation, can only lead to a state of things more offensive than at first, and mark out the object of this immature aggrandizement as one, perhaps, of desire to the avaricious and selfish, but of disgust to every well-regulated member of society.

—

FACTORIES REGULATION BILL.

THIS Bill, we regret to state, has been virtually defeated, by the manœuvres of the cotton-spinners and the Ministers last night, in altering its second and principal clause. The object of the Bill, it will be remembered, was to afford protection to young people of both sexes, under the age of 18: as it now stands, they are to be protected only up to 13; *leaving the whole period of puberty unprotected*. We blush to add that Lord Althorp, in effecting this mischievous change, was enabled to base his arguments on the dicta of the late *medical* commission

COLLEGE OF PHYSICIANS.

[We give insertion to the following letter, though there is something informal in the mode in which it has reached us. We will thank the writer, the next time he favours us, to send his name, especially when he directs his communication to a private address.]

To the Editor of the Medical Gazette.

SIR,

You have indulged yourself in remarks frequently, of late, on the unpopularity of the College of Physicians. Is it true that this learned body is so unpopular in public opinion? I would deny the fact in the first instance; for, by your own Gazette, it appears that the meetings of the College have been well frequented, not only by the medical profession, but by the most eminent members of the law and the church, and by the nobles of the land. And as to the papers to which these audiences have been called to listen, your own pages will furnish ample proof of their interest and value.

In respect to the liberality of the College, on the want of which your imputation might be expected to rest, if you take the trouble of referring to the returns made by the College to the orders of the House of Commons, dated June 21st, you will see, in the first place, that within the last ten years no fewer than seven of the Licentiates have been elected into the Fellowship; and that, towards the expense of the present building of the College, not less a sum than 8,000*l*.* has been actually subscribed by the present Fellows. And what use have they made of the building to which they contributed so largely? What except to open it to the public, and to cultivate a good understanding amongst the several branches of the profession?—I am, sir,

Yours, &c.

A FELLOW OF THE COLLEGE OF
PHYSICIANS.

[It is one thing to act with a certain intention, and another to succeed in it. Of the "good intentions" of the College towards the public and the profession, we entertain little doubt; how far they have been successful in effecting their benevolent purpose, is another question. The want of "liberality" usually imputed to the College, is quite another thing from what our correspondent seems to suppose, and has but little reference to pounds, shillings, and pence; and for the seven Licentiates we have always given them ample credit. As to their "unpopularity"—however it be accounted for—we have only stated the fact, and as a fact much to be regretted. We can hardly think our correspondent serious, when he appeals to the "meetings" as a proof of the popularity of the College. Did it never occur to him to classify the visitors at any of the well-attended *conversazioni*, and to analyse the probable motives of their coming?—E.G.]

HOPITAL DE LA CHARITÉ.

CLINIQUE OF M. BOUILLAUD.

Case of intense Peripneumony successfully treated — Relapse during Convalescence — Choleric Dysentery — Death — Autopsy. — Reported by M. Donnè, Chef de Clinique.

THE following case of severe peripneumony is interesting, chiefly on account of the accidents which occurred during convalescence: such accidents are by no means rare in our hospitals, but they are too commonly disregarded. It will be seen, in short, that too much care cannot be bestowed on the regime of patients during their recovery, and even long after they have escaped the principal danger of their disorder.

Bruneteau, a mason, aged 18, just arrived in Paris, was taken to the Charité on the 27th of March last, labouring under a peripneumony which involved a large portion of the right lung. The patient is of a rather robust constitution, of pretty full habit, and presenting every appearance of habitual good health; has never had any severe illness before, and is subject to no infirmity; not given to excess of wine or strong liquors. He left the department of La Creuse to travel to Paris on foot, and on the way received much rain while in a heated condition. On the 25th of March he arose as well as usual, without either cough, shivering, or pain in the side; he then went to the Grève in search of work, where, having been ex-

* From this document it appears that the expense of building the present College amounted altogether to more than 25,000*l*. Of this sum, 9,000*l*. were the produce of the sale of the building of the College in Warwick-lane, and 2,000*l*. were given by the Radcliffe Trustees. The rest was provided by the contributions of the present Fellows, and by the ordinary revenue of the College permitted to accumulate during several years for this particular purpose.

posed for some time to the cold, he was taken with shiverings, and returned home to bed. Presently he felt a pain in the right side of the chest, increased by strong inspiration and by coughing; the sputa which he began to cough up were at first white and mucous, but next day assumed a rusty colour, became viscous and semi-transparent. Intense headache; four or five stools in the day; sleepless; shivering, then burning with heat. Next day the symptoms aggravated. He reached the Charité in the middle of the day, and was bled in the evening; four *palettes* of blood were abstracted; the clot, when examined the day after, swam in an abundance of serosity, and shewed traces of a greenish buff.

When visited on the 28th, he was lying on the left side; the pain in the right preventing him from lying on that side. The head heavy and painful; no delirium; sighing; sleepless; lips dry; tongue moist, coated white in the middle, with red edges and apex; thirst.

Examination of the Chest.—Respiration embarrassed—44 in the minute; cough frequent; expectoration scanty. Breath fetid; sputa slightly streaked with blood. Sharp pain of the right side at the base of the chest, below the arm-pit. The resonance can be perceived in front, to the distance of two fingers' breath below the nipple; there a decided solid sound is observable, which I should consider owing to the presence of the liver; but the respiration is pure and vesicular in the former part. Behind, the clear healthy resonance is discernible to below the middle of the chest—in fact, to four fingers' breadths below the scapula; there commences a strong bronchial respiration, with resonance of the voice and ægophony. On the side, below the arm-pit, towards the base of the lung, the same respiratory sounds. An examination of the left side shewed the respiration and resonance there to be perfectly healthy. The sounds of the heart dull and deep: no pain on this side.

The patient was immediately bled afresh to three *palettes*, and twenty-five leeches were applied to the seat of pain. Poul-tice, emollient lavement, low diet. Pulse springy, regular, 96 in the minute. Pit of stomach and right hypogastrium painful on pressure. Eight liquid stools, without colic, in the course of twelve hours. Considerable heat of skin, without dryness. Another bleeding in the evening.

29th.—The blood covered with a thick greenish buff. Pulse 100; respiration 40 to 44. Sputa rather scanty—still rusty. Crepitous râle in a limited spot behind, at the base of the lung. The pain of the side less severe. Skin dry, with a slightly jaundiced tint. Bleeding again; twenty leeches to the side; diet, &c. as before.

30th.—Prostration since yesterday. No buffy coat on the clot. Pulse 112. The respiration discernible through the whole extent of the inferior lobe of the right lung, with crepitous râle very distinct. Bleeding to three *palettes*; 15 leeches.

31st and April 1st.—Leeches repeated each day. Less prostration. Patient complains.

2d.—Skin less hot and more moist. Figure calm. Pulse 92. Respiration calm.

From this date the cure proceeded rapidly: on the 6th, no blood was discovered in the sputa. Respiration of the right lung scarcely discernible from that of the left, except by its being somewhat more feeble. Broths and soups. Convalescent on the 10th.

On the 13th, the patient gorged himself with food, which was probably brought to him by some of his friends: he afterwards went down to the garden, remained exposed to the sun for a time, and then was seized with vomiting. Every symptom of fever was present next day. Leeches to the temples: low diet. On the 15th, numerous stools, tinged with blood. Excessive weakness. Leeches to the anus: starch lavement.

Next day the stools were almost continual, and consisted of nearly pure blood, with white grumous masses floating in it. The evacuations much resembled those in cholera at an advanced stage. Very little urine, but no cramps. The patient sunk at noon.

Autopsy, 24 hours after death.—Both lungs healthy and natural, with the exception of a few adhesions to the pleura costalis of the right side.

The stomach and digestive tube, even as far as the end of the small intestine, showed no alteration worth noting. There were a number of follicles enlarged towards the end of the jejunum, and four lumbrici were observed.

From the large intestine there flowed a considerable quantity of sanguineous fluid, of the consistence of bouilli. The mucous membrane riddled with red spots, swollen, and softened to such a degree as not to bear raising in the shape of a flake. The submucous cellular tissue natural. The morbid change just noted was most conspicuous beyond the transverse arch of the colon. Remarkable signs of hæmorrhage were discovered in this latter part of the bowel.

REMARKS.—The antiphlogistic treatment was employed here with equal energy and success. The fatal accident which took place during convalescence ought not to depreciate the good effect of bloodletting in this sort of pneumonia. It is very remarkable that after five bleedings practised in four days, and the application of sixty leeches, the strength rallied and the pros-

tration gradually disappeared. This is an example of the general practice adopted by M. Bouillaud in the peripneumonies of young and vigorous subjects: he is of opinion that this mode of treatment cannot properly be appreciated, except when it has been employed thus energetically: cases like those described by M. Louis, in his interesting memoir, where but two or three bleedings have been abstracted in the beginning of the disease, cannot serve for good examples.

It may probably be asked whether the sanguineous emissions in this case, carried to the extent described, did not render the convalescence more difficult? whether they would not have rendered even the very slightest relapse dangerous, if not fatal, through want of power of re-action in the patient? All the answer I can give to this query is, that the preceding case presents the very first accident of the sort that I remember to have noticed out of the very large number of peripneumonias which I have seen treated in the service of M. Bouillaud.

A LIVE MOUSE SWALLOWED.

THE following case is related by Dr. Heyman, of Oldendorf. It occurred not long since in the village of Lashorst, in Westphalia. A child about three years old was put to bed, having not yet quite finished its evening meal. The mice, with which the house swarmed, were presently attracted by some crumbs of bread which were about the child's mouth. One of the hungry marauders even ventured within the lips, and in the child's alarm, on a sudden effort to awake, was swallowed. There was now, of course, much screaming, and the extraordinary story was told by the child, that a mouse had gone into its mouth: the region of the stomach was pointed out as the seat of pain, which was confirmed by the writhing and the spitting of blood which presently ensued. The pains lasted in all their violence for two hours: then came at last a repose, interrupted, however, now and then by further writhings and spitting of blood. Next morning a large quantity of milk was given the child. All this time it was greatly doubted whether any such thing as a mouse had been really swallowed. But in forty-eight hours, a mouse of considerable size was found to have passed by the bowels: it was greatly mashed, and had the hair stripped off on several parts of the skin: it was enveloped in mucus and blood. The digestive organs suffered very much from this accident, so much so, indeed, that the child was for some time after seriously ill, though at present the recovery is perfect.—*Beilage Medicinische Zeitung.*

COLLEGE OF SURGEONS.

MR. GUTHRIE has been elected president, and Messrs. White and Andrews vice-presidents for the ensuing year.

CUVIER.

At the public annual meeting of the Academie de Medicine on the 9th instant, at Paris, the bust of Cuvier was set up in the great hall of the Institute, and an able *éloge* pronounced upon his memory by M. Pariset.

ANOTHER CONCOURS.

A NEW concours was opened at Paris on the 12th instant for the chair of *Pathologie externe* in the Faculty. MM. Sanson, Velpeau, Gerdy, and Lepelletier de la Sarthe, are among the candidates. Strong protests and reclamations have been presented to government against the issue of the last contest.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

—
DISEASES OF THE STOMACH AND
INTESTINES.

—
STRUCTURAL DISEASES.

BESIDES common inflammation and its effects, with which you are now acquainted, the stomach is liable to peculiar structural diseases. Scirrhus, open cancer, encephaloid disease, and melanosis, will occur in the stomach, and they will all take place in various parts of it, but they most frequently take place at the cardia and the pylorus. This accords with the general rule that I mentioned, namely, that the orifices of cavities are most frequently the seat of structural disease.

SCIRRHUS.

Symptoms.—When scirrhus exists, there may be pain at the spot which is affected, and that pain may go through to the back, and be increased on taking food. Besides pain, there may be all the symptoms of indigestion, and there may be great nausea and vomiting, so that nothing can be retained on the stomach. If it be the cardia which is the seat of the affection, the food is generally rejected immediately. I have seen an instance where the moment the food reached the cardia, a heaving took place, the patient felt as if he were being destroyed by wind, and he said the complaint was nothing but wind. Sometimes the food will pass the cardia, and be rejected immediately, or five or ten minutes afterwards. But if it be the pylorus in

which the disease resides, then, in general, the food will be retained some time, perhaps half an hour, or perhaps more; there is no general rule.

There may be pain in the region of the cardia, pain in the region of the pylorus. In the case of the cardia, you may find great difficulty in passing a probang into the stomach, for there may be a stricture at the part; but when the pylorus is affected, there is not only severe pain in that region, but at last there is a tumor. There is generally in that case emaciation and a sallowness of look, such as I told you might be called *cancerous cachexia*. Sometimes the vomiting which takes place is very offensive, sometimes bloody, and sometimes the eructations are exceedingly foetid.

Nothing, however, is more common than to have dreadful disease in these parts with scarcely any symptoms whatever. Every practitioner must have seen extreme disease in the stomach, great ulceration of it, decided cancerous and other malignant diseases of this part, without pain worth naming, without any vomiting till just before death, and without any other symptom than perhaps extreme weakness, paleness, and some obscure uneasiness about the stomach, and perhaps not even that. It is sometimes quite extraordinary to open stomachs, and see the disease which exists there without any symptoms having taken place, or symptoms of a very slight character.

When the pylorus is affected you occasionally have jaundice, from pressure on the lymphatic duct or the choledochus. Occasionally in this disease, as well as in an affection of other parts of the stomach, there is vomiting of a very foetid secretion, and sometimes of blood, and the blood will pass through the pylorus to the intestines, so that it will appear in the motions.

Any local symptom may be absent.—There is not one of the local symptoms of this complaint that may not be absent. Some

times there is no vomiting, sometimes there is no pain, and it is only by a very careful observation,—indeed, by considering that there are no signs of derangement of other organs, that we frequently make up our minds that the disease is probably situated in the stomach. Sometimes there is very little more than dyspepsia, and sometimes people eat well, and are but little troubled with indigestion; but at last there is generally more or less hectic.

Occurs at any part of the organ.—These scirrhus formations and cancerous ulcerations, as well as other organic diseases, may of course exist at any part of the stomach as well as at the two extremities, and the symptoms are generally the same.

Symptoms rendered obscure by the absence of obstruction.—The symptoms are much less likely to be observed in the stomach, if no obstruction is produced. If an obstruction be produced in the pylorus, then you have disturbance; or if it occur in the cardia, there is great difficulty of swallowing, and great pain when the ingesta reach the part. In the case of the pylorus, the stomach becomes so distended from the difficulty with which the contents pass out, that vomiting generally occurs. It is generally noticed that when there is an obstruction at the pylorus, either from scirrhus or any other disease—but scirrhus is the most common—the stomach acquires a very large size, it becomes immense, from the difficulty with which the contents pass through.

Morbid Appearances.—If scirrhus exist generally in the stomach, the organ of course becomes very thick throughout, and its cavity is diminished; the mucous membrane looks puckered and ulcerated. When the disease is situated about the pylorus, it may occasion the stomach to become of an immense size; whereas, if it exist throughout the stomach, it may produce very great contraction; for scirrhus causes a shrinking, and produces a contraction of the parts all around, which spreads throughout the stomach, and in the case of the pylorus, it produces such a contraction there that the food will not pass through.

Stricture independent of malignant disease.—Dr. Baillie mentions that occasionally there is simple stricture of the pylorus or the cardia independent of malignant disease. These two parts are subject to stricture just as the urethra is, without any organic disease whatever.

Treatment.—In regard to the treatment of this affection, it is of course mere palliation. You have to support the patient's strength and give narcotics, to alleviate the suffering and vomiting. There is no medicine with which I am acquainted that produces so much alleviation in these or-

ganic diseases as hydrocyanic acid. It frequently arrests the vomiting for a length of time; but it always lessens it very considerably. If there be very great pain, it is necessary to employ opium, in order to reduce it. I have used iodine in these cases, and I have thought with a certain degree of advantage. In one case of scirrhus pylorus, I exhibited iodine and prussic acid together, and the disease appeared to stop. I have no doubt that the patient laboured under scirrhus pylorus, for I felt the tumor, and the patient had a sallow look, and vomited for a length of time. I gave him these medicines as a forlorn hope, and he was much better; but in a great number of cases, I have not seen any such result as this, and sometimes there has been no benefit whatever.

In regard to stricture of the cardia, some good may be done by mechanical means, by passing a bougie, taking care not to pass one so large as to occasion suffering to the patient. In the case of a contracted rectum, benefit has been said to be derived by the passage of a bougie. Although organic disease cannot be remedied, yet the effect of it in lessening the canal may be diminished, but great care should be taken not to employ it so as to cause injury.

I believe I mentioned in regard to stricture higher up—in the œsophagus, that sometimes there is a scirrhus, and sometimes only a common stricture; and that besides these diseases which can be treated only by a common bougie, the parts are subject to spasmodic stricture. The latter case occurs particularly in females, who will sometimes be unable to swallow for weeks together, and then they will swallow very well. These cases are to be treated by improving the general health by the cold bath, and a pleasant occupation of mind.

CALCULI.

Calculi have sometimes been found in the stomach, but for the most part they have been biliary calculi, which have got there either by ulceration, or by passing upwards through the pylorus; one which was examined was found to be cholesterine. I shall speak hereafter of concretions of the alimentary canal at large; but you will find that some authors mention that calculi have been discovered in the stomach the size of a hen's egg. I never myself saw a stone in the stomach.

HÆMATEMESIS.

There is one disease to which the stomach is very liable, and that is hæmorrhage. Without the presence of any malignant disease, without any organic disease, frequently without any inflammation that can be discovered, and frequently

without any danger whatever, a quantity of blood is discharged into the stomach, and it is usually dark, and in large clots. When speaking of hæmoptysis, or spitting of blood, I stated that one could not infer, because in these cases the blood was black, that it was venous blood; for if arterial blood be poured forth into a cavity, and lies there, it will acquire a venous character. Its nature is not to be ascertained from the colour; but when you consider that patients will pass a vast quantity of blood in this way, it is easy to conceive that it proceeds from the veins, where the motion is very slow. If it came from the arteries, one cannot but conceive that patients would suffer much more depression. We know that a great quantity of blood is sometimes discharged from the pelvis, flows from the lower part of the alimentary canal attended with no very great loss of strength, and there the blood is for the most part black.

Symptoms.—Hæmatemesis, however, is usually marked by nausea and vomiting; if not by the latter, yet by the former, and by the sensation of a load at the pit of the stomach—at the epigastrium and hypochondrium; and sometimes more than that, there is great pain there on pressure. The blood, besides being thrown up by vomiting, is frequently discharged by stool.

Causes.—This disease occurs very frequently in persons who are dyspeptic. I do not mean to say that dyspeptic persons have this affection, but those in whom it occurs frequently are dyspeptic. It is an affection that occurs far more frequently in females than males, and it is common in women whose catamenia are suppressed or diminished. It will in some persons return at intervals, and occasionally it is periodical.

The ordinary form of the disease, like a great discharge of blood from the intestines themselves, is for the most part without danger. Persons may die from it, but for the most part they recover; still it may be a very dangerous disease. It may proceed from an ulcer, and you may not be able to stop it; but for the most part it would appear that great congestion has gradually taken place in the neighbouring parts—in the stomach, and most probably in the liver and spleen, and all around; and then this blood, half out of the circulation, is poured forth, and nature is very much relieved by it. It is, for the most part, a passive hæmorrhage.

It sometimes arises from an obstruction in the liver and spleen, as well as from the want of secretion by, or discharge from, the womb. It is frequently observed in hepatic and splenic diseases. The danger chiefly depends upon the source whence the

hæmorrhage proceeds. An aneurism of the aorta has sometimes opened into the stomach, and given rise to the disease. Occasionally this hæmorrhage is only a part of the affection called *purpura hæmorrhagica*, of which I have formerly spoken.

I once saw a patient die from this affection in a minute or two. I was not aware that he had hæmorrhage before, but he had some pulmonary complaint; he suddenly fell back, and died in a minute or two. Blood came from his mouth, and on opening the stomach it was filled to the utmost with blood, which formed a large mould of the organ. I could discover no disease whatever of the part, or any vessel that let it forth.

Morbid Appearances.—Sometimes, in this affection, the surface of the stomach within is pale, and sometimes it is in a state of great congestion.

Treatment.—In regard to the treatment of hæmatemesis, it may be necessary to take blood from the arm, or it may be necessary to apply leeches plentifully all over the stomach, and then to order blisters. But for the purpose of stopping the hæmorrhage it is best to give the patient cold drinks, and, if you can, ice water. You should give him scarcely any food, and not only take care that what he drinks is aqueous, but as cold as he can bear it. The oil of turpentine is one of the very best remedies you can employ: I do not know that I ever failed in stopping hæmorrhage of the stomach with it. It should be given in a small quantity—twenty or twenty-five drops every six or every four hours. If it should create sickness, you will find it of advantage to unite hydrocyanic acid with it. They may be given conjointly, or you may give the acid a few minutes first. The acid has not the power of stopping the hæmorrhage, but if there be any nausea it enables the stomach to bear the turpentine much better. I have the highest possible opinion of lead in passive hæmorrhage, but here you can apply the oil of turpentine to the spot which is the seat of hæmorrhage; and although I never saw it do good in hæmorrhage from the lungs, yet it is superior to lead in the case of the stomach and intestines. The effect of it, when it comes in immediate contact with the part, is very great; but still it is necessary to keep the patient perfectly quiet. I have had a large number of cases of this disease within the last twelve months, and I believe every one of them has done well. I do not remember a case where the turpentine had not a decided effect in stopping the hæmorrhage.

Dyspepsia referred to derangement of the Digestive Organs.—The preceding are the diseases generally of the stomach, with the excep-

tion of dyspepsia, which is so connected with an affection of the liver and alimentary canal, that I will bring them altogether under one name, and call them *derangement of the digestive organs*, and speak of them on another occasion.

ACUTE ENTERITIS.

We will now pass the pylorus, and first consider inflammation of the intestines.

Symptoms.—In simple enteritis, supposing it is active and violent, you will have acute deep-seated pain, and this may occur in various parts of the intestinal region, and of course it is increased on pressure. Although the pain is constant, yet it is aggravated at intervals. It differs from “a fit of the gripes,” as it is called—pinching and purging—in this, that in common pinching there are intervals of ease, and when the pinching is over the person is comfortable; whereas, in enteritis, although the pain comes on at intervals, yet it is constant—although it is not of uniform intensity, yet it is always present. This is an important thing to observe, because I have seen persons seized with tormina which required brandy, or at least laudanum, and then gradually the tormina became constant, and there was pain increased on pressure, whereas before it was rather relieved by it. When this change takes place, laudanum and brandy would not only be useless but increase the pain, so that bleeding would be required. I recollect one case where I was with the individual the whole time, and the series of changes were quite manifest.

There is usually in this disease, where there is this sharp fixed pain, great costiveness. The abdomen, after a time, becomes tense, and from the severity of the pain there is anxiety of countenance. The tongue grows white, and the breath is quickened. Nausea and vomiting soon occur, and if complete obstruction take place, you may have vomiting of faeces. This occasionally happens, and formerly a particular name was given to it—“the iliac passion,” *passio iliaca*. The patient lies on his back, just as in peritonitis, with his body drawn forwards and his limbs drawn up. The patient lies quiet, for if he move about he increases the pain. A patient is often disposed to be restless throughout, but for some reason he cannot. In these cases the patient keeps his body still, but tosses his arms about. The pulse, of course, becomes quick, and it is generally small, and sometimes hard. It is generally in cases of this kind that we have what is termed a *wire* pulse—that is to say, it is as small and as hard as wire. A *thready* pulse is one where it is as small and as soft as thread. The tongue at last grows brown, and ultimately (provided

things go on from bad to worse) the pain all ceases, the patient will often bear pressure, the abdomen swells and becomes very large, and if you place your fingers across it, and strike it, the sound is as hollow as a drum. The patient then becomes exceedingly restless, and delirious; the pulse becomes irregular, and very rapid; the respiration is also quickened, and death ensues.

Morbid Appearances.—After death, you will very likely find no effusion whatever, but mere redness. Sometimes, however, you will find an effusion of lymph upon the surface, and more or less serum, from the peritoneal coat having suffered with the rest. From the great congestion, sometimes a portion of the intestines will be almost perfectly black—as black as any blood can be. This has continually been mistaken, as Dr. Baillie mentions, and as I stated when speaking of inflammation in general, for gangrene; but you find that it resists the fingers in a way that gangrene would not. You know how mere congestion will make a person black in the face; but there *may* be gangrene, though it is a very rare thing. I do not recollect seeing it. The parts become lacerable like paper, as well as black, and smell intolerably. Occasionally pus has been found in the substance. You have the mucous membrane within, and the serous membrane without, inflamed; but the chief seat of this inflammation, producing this obstruction and this violent pain, I believe is the cellular coat of the intestines. I have never seen the muscular fibre in a state of inflammation; it may be in a state of hypertrophy, but I have never seen it inflamed. Acute rheumatism is for the most part inflammation of the aponeuroses, even when it appears to be the muscle itself which is affected. Rheumatism, generally speaking, affects parts which are not muscle at all; but if the muscle be affected by it, it is only secondarily. We never have an effusion into muscle, nor suppuration, nor any thing of the sort. It appears to me that it is the cellular membrane of the intestines that is chiefly the seat of this disease, although the peritoneal coat, and the mucous membrane, may be also inflamed. It is said that pus has been found in these cases in the very centre of the intestines: this I have never seen.

Diagnosis.—Enteritis is distinguished from peritonitis by the obstruction that is produced, the constipation, and the consequent effects of it, nausea and vomiting, and also by the circumstance of the pain being fixed particularly about the umbilicus, which is generally the seat of it, whereas in peritonitis it is diffused.

Causes.—This disease is caused by any

thing which will produce inflammation—cold and wet applied externally, and cold internally; and it is induced by any thing which occasions obstruction. If there be a hernia, and the part becomes girt, then you have enteritis. If the faeces become black and indurated, and will not pass, then you may have this disease. Whatever causes an obstruction is sure to produce this affection, if it continue sufficiently long for the disease to be set up.

When you are called to a patient in this disease, before you think of any thing else you must first ascertain the cause. You must examine every part of the abdomen, and see whether there is not an umbilical or ventral hernia; for patients continually have symptoms of this description because there is a hernia, and the hernia may be so small as to escape attention. A small portion of the intestines may slip down without the patient knowing it. Great mistakes will occur if persons do not remember that this disease may be the result of hernia, and that a patient may have hernia without knowing it.

Treatment.—If there be a hernia, that will be treated in the way which the surgeon thinks best; but if there be not, the first thing which you have to do is to bleed the patient well. You should set him as upright as he can be, and bleed from a large orifice, without any mercy. You must of course consider the patient's strength; but you should bleed on till you make a decided impression, till you knock down the pulse and make him faint. After this has been done, undoubtedly a very large dose of calomel should be exhibited. A large dose will clear the stomach as well as a small one, and it will be more effectual in purging. After it has been taken some time, other purgatives should be given; but immediately after it is administered an active injection should be given, so that if possible they may meet half-way and combine, and then out goes the disease. You should first bleed very freely, because purgatives will not operate till you have done that. You should then give a large dose of calomel, such as a scruple, by the mouth, a strong purgative injection, plenty of salts—if you choose, salts and senna, or colocynth, or oil of turpentine—and I would repeat the calomel in smaller doses, say ten grains, every four or six hours, giving purgatives in addition from time to time, till the mouth is sore; and in general when the mouth is sore, and the bowels are freely open, the inflammatory symptoms go away; and as the obstruction frequently arises from mere inflammation, if you remove the latter by bleeding and producing a mercurial affection on the patient, the former will subside.

It is also well to cover the whole abdomen with leeches; twenty, thirty, or forty should be put upon it; and if nothing will open the bowels—if you have given mercury till the mouth is sore, and followed it up by other purgatives, such as croton oil, which is one of the best, and of which a drop may be given every two or three hours (sometimes I have given a drop every hour), then you will find it of very great use to employ the smoke of tobacco. A tobacco clyster is sometimes a dangerous thing, and you should only put a drachm to a pint of water, and throw up one-half of it, and watch its effects; but the smoke of tobacco is very manageable. There is a little apparatus for the purpose. You can feel the pulse at the same time, and regulate the smoke proportionately at your discretion. Sydenham was very fond of this, but not more so than the remedy deserved. He says that the smoke of tobacco was by far the most efficacious of all the injections that he knew. I know many practitioners who now employ this with very great success. If this fail, there is no impropriety in taking the patient out of bed, and throwing a few pails of cold water hard against the abdomen: that will sometimes open the bowels when nothing else will. But where you find inflammation, and no mechanical cause that you can discover, the best mode is to treat it as an attack of inflammation, but in the most decided manner. You must take care to give purgatives as abundantly as the stomach will bear them, till they produce their effect.

This disease is called enteritis, as it is an inflammation of the substance of the intestines; but similar symptoms in many respects are produced by mere spasm—that is to say, perfect obstruction, together with vomiting and violent pain, but pain of a different character, and then the disease is termed colic—enteritis being essentially inflammation, but colic being essentially spasm; but when the spasm ceases, then inflammation may come on, and you have a case of decided enteritis.

COLIC.

Having spoken of that description of obstruction of the bowels which is inflammatory, I now proceed to consider that which depends simply upon spasm. This obstruction of the bowels is called *colic*.

Symptoms.—The symptoms of colic are, in the first place, constipation, with violent pain in the region of the intestines, chiefly, as in other cases, about the umbilicus. This pain, unlike that induced by inflammation, is relieved by pressure, for there is no tenderness. The relief is sometimes very great upon pressure; at any rate, pressure is always well borne. I have

sometimes pressed with the whole weight of my body, raised myself on tip-toe, and the patient has not complained at all; on the contrary, he has felt better. The pain is of course intermittent—it is not uniform, nor, indeed, is it constant; it will cease from time to time; the person will be perfectly easy; and then it comes again most terribly. In most cases there is vomiting—at any rate, nausea. The vomiting may be faecal—the faeces have been discharged upwards, as in cases of inflammatory constipation. In either instance, however, this circumstance is comparatively rare. The spasms in these cases are not confined to the intestines, but you will frequently see them in the abdominal muscles, so that they shall be drawn into large lumps. The recti muscles become particularly contracted, and you will sometimes observe retraction of the navel. Sometimes there is tenesmus, and sometimes there is great contraction of the sphincter ani. There is violent pain felt likewise in the loins, there is a high degree of flatulence, and there is no feverishness.

Induces Enteritis.—It is carefully to be remembered that this state of things, however purely spasmodic it may be, will frequently, if not relieved, run by degrees into enteritis, so that at last you shall have decided inflammation of the intestines.

Causes.—The causes of this disease are, in the first place, the application of cold when the body is overheated: this is a very common cause. Ingesta of various kinds, which disagree with the stomach, will give rise to it. Sometimes I have seen it occur from a person taking bad cyder; but in other cases it will take place, not from any thing injurious in itself, but from an individual having an idiosyncrasy in regard to it. Obstruction from any cause will produce it. If there be a hernia, colic may be induced, in the first instance, before inflammation comes on. Hardened faeces is another cause of the disease: it is a common occurrence from any of those causes which after a time produce enteritis. Sometimes you will have enteritis first and then colic, and *vice versa*, though the cause of both one and the other may be the same. A very frequent cause of it is a particular substance, viz. lead. In some persons a very minute portion of it will induce this affection. A medical man told me that he had it from a child's cot, newly painted, being placed in his bedroom. You see the affection every day in painters, and in persons employed in the manufacture of white lead. Individuals exposed to lead in any way are very subject to this disease.

Morbid Appearances.—After death you may find nothing at all. Whether the disease has arisen from cold, from acrid in-

gesta, or from lead, you may find no morbid appearances whatever; but, on the other hand, you sometimes do. This is all a matter of chance. Sometimes the intestines are in a state of great contraction—sometimes they are more or less inflamed, because the disease has terminated in that way. Sometimes you find the cause to have been something sticking in the way, or mechanical pressure of some kind, or you may find intus-susception, one part of the intestine running into another. In regard to the appearance of the muscles, they are emaciated, thin, white, and pale. I have seen the muscles so flabby and wasted that you could scarcely recognize their natural appearance; they have become little more than tendons. When intus-susception has been the cause, you generally find that the upper part of the tract has passed into the lower. Dr. Baillie has given some good representations of intus-susception.

Treatment.—Colic may generally be treated very successfully by the exhibition of purgatives in strong doses. If the individual be stout, and the pulse will bear it, it is a good practice to bleed him. Bleeding is an excellent anti-spasmodic within certain limits; spasms of various parts of the body will continually cease on taking away blood. It is not always necessary in this affection, but it may be successfully had recourse to, if the pulse will justify it, even though it may not indicate it, and it may also act beneficially in preventing inflammation. It is very useful to give a large dose of calomel, to administer a scruple repeatedly after longer or shorter intervals; and after you see that it will remain on the stomach, then it is right to give some other purgative—a strong dose of castor or croton oil, and Epsom salts. One of the best purgatives is undoubtedly croton oil; and if you choose you might begin with it, but it will be of little use to give less than a drop. In severe cases I would repeat it every hour or two till it answered the purpose. Last summer I was called to a case where the hot bath and every medicine in common practice had been used excepting croton oil; a dose or two of that, however, had been given. But the case was very severe, and it was necessary to overcome the disease speedily, and I therefore ordered a drop every hour or half hour till it operated. After about six doses the bowels were freely opened, and the patient became perfectly well. An injection of oil of turpentine will also be found exceedingly serviceable. About three ounces, diffused in a pint of fluid, and forced into the intestines, is of great service. The warm bath will afford great relief, but it is rather of use as a soothing measure than any thing else. The great

point is to give good purgatives, and croton oil is certainly one of the best; but you may precede it, by way of laying a foundation for its action, by a large dose of calomel. At the same time, whatever good may be done, you should not omit clysters, and I think you will find the oil of turpentine one of the best. Some persons always combine opium with the calomel, and the opium may frequently do good in alleviating the spasm. This is a case in which opium may act as a purgative; by relaxing the spasm, it may cause the bowels to open, and it is thought that it very much reduces the pain, and makes purgatives and calomel stay better on the stomach. It is therefore said that we ought always to give a larger or a smaller dose of calomel—a scruple or five grains, whichever you may have a fancy for, united with opium, and repeat it at certain intervals; but I have found the bowels open just as well without opium, and there is no trouble afterwards. If you exhibit opium, after a time the bowels are disposed to become torpid, and I am quite sure that you will succeed as well without it as with it.

When every thing has failed, I have known this affection of the bowels overcome by taking the patient out of bed, and dashing two or three pails of cold water upon the abdomen. In the particular case to which I have just alluded, though the patient had taken calomel till his mouth was sore, before we began with the croton-oil, as the object was to open the bowels immediately, he was taken out of bed and soused with cold water, and he was nothing the worse for it; he caught no cold, but it did not open his bowels. Sometimes it will effect that object immediately, just as it will relieve spasmodic stricture. If all other things fail, it should be had recourse to. You will also find the smoke of tobacco exceedingly useful in this affection. It should be used as I have before mentioned. Some have even found the inflation of common air serviceable, by producing a great distention of the intestines. You will find a case of this kind recorded in the Glasgow Medical Journal of last year. It is well also, on another account, to administer a clyster, for sometimes the symptoms arise from hardened feces lodged in the rectum. I have known instances of that description; and as you do not always know whether such an occurrence has taken place on that account alone, I would invariably recommend a clyster. Occasionally, it is discovered, especially in women, that there is a mass of large hardened feces there, and nothing will relieve the patient but taking the handle of a spoon, and picking them out.

Practitioners are sometimes obliged to condescend to this, and clean out the rectum.

Tendency to return when induced by Lead.—Supposing, however, that the disease has arisen from lead, you will find it has a great tendency to return. There is this tendency under all circumstances, but particularly in the case of lead; so that after you have once opened the bowels, it is necessary every day, for some time, to ascertain that the bowels are still regularly opened. Some German writers, and Dr. Percival, of Manchester, have praised alum very much. They state, that from two grains to a scruple has been given every six hours, with great relief: however, I should never think of depending upon such a remedy in cases of colic. It may be very well after the attack is over, for the purpose of keeping the bowels open; but I should not think of placing any reliance on it during the fit. I know that it has been useful, for I recollect perfectly well having been consulted by a gentleman who, every six weeks or two months, had a violent fit of colic, so that it was necessary to put him in the hot-bath and exhibit a violent dose of purgatives. This always cured him, but left him in a state of great debility, and nothing that was done prevented the recurrence of the attacks. I gave him a scruple or half a drachm of alum three times a day, mixed with ipecacuanha powder, well diluted, and it entirely cured him. He took it for a month or six weeks. I saw him for three or four years afterwards, at intervals, and he had never had another attack. I dare say that ordinary purgatives in most people will do very well, but I tried alum in this instance with great success. You will find it useful, where there is a tendency to disease of the intestines, to put the patient on his guard with respect to cold, and order him to wear flannel about the abdomen. A large roller, wound three or four times round the body, is exceedingly serviceable. This protects the abdomen against cold, and it is always useful. In this, as in most other bowel complaints, it is particularly necessary that the patient should avoid cold feet; for some individuals, if they allow their feet to become cold, always have an attack of colic. When the disease has arisen from lead, you will sometimes see the stomach remain in a state of spasm, so that there will be an aching pain there, and occasional vomiting, notwithstanding the bowels are regularly opened. This is a state which is best relieved by prussic acid or stramonium.

PARALYSIS AFTER LEAD-COLIC.

When the disease has been induced by lead, you will sometimes find that after

the colic is over the wrist will drop; the muscles situated in the forearm, and belonging to the hand, become paralysed; so that the patient has very little use (perhaps none) of the hand, and the muscles will at last waste away. It is said by some writers that the abductor pollicis wastes more than the others; but I am not aware that it does. Sometimes this will occur from lead without any colic at all; but generally there is colic, and this is followed by paralysis of the wrists.

Treatment.—Now this is a state that may easily be remedied. In the first place you should withdraw the person from the poison, and prevent him for a time from following his occupation; if he be a painter, you should withdraw him from the lead, or the lead from him. It is also of great importance that he should not wear the clothes which he uses in business: a quantity of lead is still remaining upon them, and that may of course keep up the disease. I have no doubt that many painters might avoid the complaint if they were more cleanly—if they wore sleeves over their coat, and as soon as they had done work regularly put off their working clothes. You cannot, however, persuade men to do this; they will not give themselves the trouble till they have once suffered for their negligence, and even then, as soon as they recover, they become careless. If painters would adopt the precautions I have given, no doubt many of them would escape.

In the way of local application, electricity is one of the best remedies. It should be applied not only to the hand, but to the forearm; because the muscles in both parts are paralysed. I think I have seen sparks answer better than shocks; and the electricity should be applied, if possible, every day. It has also been recommended that the patient's hand should be supported by splints, and that these should be used night and day, so as to keep the hands in a state of constant extension. You will find this recommended by Dr. Pemberton. Blisters are also said to be useful. I have found stimulating applications of all kinds serviceable, but particularly electricity. When you apply stimulating applications on the skin, they only act within sympathetically; friction may make the parts worse, but electricity will go to every spot which is really the seat of the disease.

As to the internal medicines, I have never seen them do good, except it has been strychnine or stramonium, or (which is the same thing) nux vomica. This is a species of paralysis wherein I have exhibited strychnine with decided advantage.

INTUS-SUSCEPTION.

Intus-susception, the affection of which

I spoke as sometimes giving rise to colic, generally occurs in the small intestines; or else the small intestines slip down into the large—into the colon. However, intus-susception of the large intestines has been seen; for the cæcum and a part of the colon have been found in the sigmoid flexure. Cases have been seen in which the small intestines from the duodenum have all slipped into the large intestines, and the cæcum has been seen to protrude from the anus. These are rare cases, but not the more impossible because they are rare.

Causes.—This disease may occur from any irritation whatever, and sometimes it has, no doubt, been temporary, and has passed away. On opening animals, you will sometimes see intus-susception take place before your eyes, and then the parts will slip out again.

Cohesion may occur.—However, when intus-susception has occurred, the parts may remain in the situation into which they have been forced, and at last cohesion takes place between the external surface of the descending portion and the inner surface of that into which it has slipped; and the mucous membrane may then cohere together, so that complete obstruction takes place, and the person dies. Sometimes the part which has slipped in has only adhered at the upper portion; sloughing has then taken place, and a part of the intestine has been discharged.

Quantity of Intestine discharged.—You will be surprised at the quantity of intestine which, beyond all doubt, has been expelled in some of these cases, and yet the patient has done well. Dr. Faillie mentions having seen, or known, a yard of the colon discharged from a woman before death: she died, but a yard of the colon was first passed. He mentions another person who lived two years after losing six inches of her colon. You may easily see how this happens without any great mischief taking place. Adhesion takes place at the upper portion of that which has slipped down, sloughing afterwards occurs, but the part remains continuous as before, only shorter. Whether the person has more frequent evacuations after the intestines have been shortened, I do not know; but it is an undoubted fact that a large portion has been expelled, and yet the person has done perfectly well. You will find another case in which twenty-three inches of the colon were discharged, and in another twenty-eight inches of the small intestines; and yet recovery took place. Cruveilhier mentions a case in which eighteen inches, together with the mesentery, were discharged, but the person entirely recovered, after having exhibited signs of strangulated hernia.

Gives rise to no peculiar Symptoms.—Now there is no proof of the existence of this condition during life: you cannot tell, in a case of colic, that the patient has intus-susception. I recollect being called to a case of violent colic, which appeared to arise from a man drinking sour cyder and rum, and a number of other things; having, in a thirsty fit, drank every thing he could reach. Violent colic suddenly took place, and his bowels from that moment were confined. He took castor oil, croton oil, olive oil, hot baths, cold baths, and every thing that could be devised, but no evacuation was produced. He survived a fortnight, and at the post-mortem examination intus-susception was found. Portions of the intestines were perfectly coherent together, forming a solid mass; so that there was no continuation between the upper portion of the intestines and the lower; but the circumstance was not known before death: there was no particular tumor to be discovered. I do not think, therefore, that in a great number of cases, from what I have read and occasionally seen in dead bodies, there can be any sign whatever, though the disease has occasionally been suspected; and, indeed, I suspected it in the case to which I have just referred. Some persons say that we ought to cut down upon the part—that we are not bound to wait for the person dying. Now the case ought to be very clear indeed before a man's abdomen should be opened, and an attempt made to untwist his intestines directly. It has been proposed by some to cut down upon the part wherever the seat of the pain is; but this is a very fallacious guide. You will sometimes have pain at one part of the abdomen, and after death the obstruction is found at another. But if, after symptoms of colic, a tumor be produced, the surgeon might then take into consideration whether he would cut down or not.

It may appear wonderful that so large a portion of intestine should be discharged; but the occurrence is not only mentioned by Dr. Baillie, who I suppose is a man who never told an untruth in his life, but you will find that Andral cites a case where thirty inches of the ileum were discharged, and death did not take place for three months, and then it arose from peritonitis. He suspected that death took place in consequence of the cicatrix being lacerated by an accidental circumstance, and that but for that, the individual would have done well. In the Edinburgh Journal, vol. ix. a surgeon mentions a case where the colon, the cæcum, and the mesocolon, were all discharged, but of course death took place.

ACUTE AND CHRONIC DYSENTERY.

I now proceed to the consideration of another disease, in which there is spasm and inflammation together, and in which there is obstruction and purging both. This disease is called *dysentery*.

Symptoms.—The symptoms of this complaint are a mixture of those of colic and enteritis, so that you have violent pains of the belly, which are called *termina*. You have also a forcing down backwards, a forcing of the rectum, which is called *tenesmus*; and frequently small mucous or bloody stools, together with more or less retention of the fæces, so that there is an obstruction to the course of the fæces, but a great discharge of secretion from the inner surface of the intestines. The stools are scanty and irregular. The discharges are very frequent, but each particular discharge itself is scanty; and when the fæces do come away at all, they are found in hard lumps. Sydenham defines dysentery to be, "frequent mucous stools, with griping." Dr. Akenside, the poet, wrote on this disease, and he gives the same definition as Sydenham; but he adds to it "frequent desire"—in fact, tenesmus.

The blood which is discharged in this affection may be either in clots, or merely in streaks; and sometimes it is discharged in a very considerable quantity, quite liquid. Very frequently there are shreds of fibrin. Sir John Pringle says that he has seen fatty matters discharged: that I can believe, for I could mention the same with respect to diarrhœa.

This disease may be acute and chronic. In the acute affection there is violent inflammation as well as spasm, so that there is considerable feverishness, quickness of pulse, heat, thirst, pain in the abdomen, not only coming on in fits, as tenesmus, griping, but likewise constant pain, and increased on pressure, together with dryness of the skin.

Duration.—This state may go off in a few days, or it may last for a month; after that time you may perhaps call it chronic dysentery.

Nature of the motions.—The liver very frequently ceases to secrete, so that no bile at all passes away; and sometimes it is in a state of great irritation, so that it secretes green bile, and the motions are therefore green. Sometimes, however, the motions appear to be of a pitch-like substance, and occasionally they are like the washings of meat. Sometimes, instead of thick mucus, there is thin serum, and from there being a little hæmorrhage it is rather red, so that the discharge from the alimentary canal has been very aptly compared to the washings of meat. The discharge may be

of all colours and of all qualities; but the faeces are usually retained. If you procure an evacuation of faeces, they come away in hard lumps, which are called *scybala*. Nature gets rid of these from time to time; they are like forced-meat balls, only hard. The tongue is of course foul, and very frequently aphthae appear, from the mucous membrane suffering.

Frequently conjoined with fever.—This disease is very common in hot climates, and most common in this country in hot weather. It is frequently united with the fevers of hot countries, and of our hot seasons, and frequently it is conjoined with intermittent and remittent fevers; sometimes it precedes, and sometimes it follows these. Sir John Pringle and Sir Gilbert Blane both say that it arises in camps at the same seasons, and under the same circumstances, as bilious fevers. It has now and then, curiously enough, been observed to be vicarious with fever. It will cease in the army and navy in different parts of the globe when fevers begin, and re-appear when they cease; but very frequently it is united with them. It has been known also to co-exist with typhus fever, and alternate with it. When typhus fever prevailed lately in Ireland, dysentery prevailed at the same time, and occasionally alternated with it. It is very common for it to occur with liver disease; and occasionally it has been united with measles. The causes of liver disease, and the causes of fever, affect all parts of the abdomen.

Chronic form less violent than the acute.—The chronic form of the disease is much less violent than the acute, and is attended with much less pyrexia; indeed the pyrexia in the chronic form may at last become hectic. The intestines become diseased, suppuration and ulceration occur, and you have hectic fever. Sometimes in the chronic form there is no fever at all, for it degenerates into diarrhoea; so that all the patient complains of at last is mucous stools and tenesmus. The faeces not being retained, it may degenerate into diarrhoea, so that you have dysenteric diarrhoea—that is, diarrhoea characterized by great griping and a discharge of mucus.

Stools more frequent during the night than the day.—In hot countries it has been observed that more stools take place at night than during the day, and at new and full moons. I mentioned, when speaking of remittent fever, that there is no doubt whatever that at new and full moon this fever prevails most, and the symptoms are more intense at that period; and the same has been observed with regard to dysentery. More stools take place at that time, not through the moon directly, but from the high tides that then take place there is more vegetable decomposition.

Morbid appearances.—After death from the acute form of the disease, we see great inflammation of the intestines, chiefly of the large ones, and particularly of the colon; this disease so particularly affects this part, that some have proposed to call it *colitis*—inflammation of the colon; but that would not be quite correct, because it also affects the rectum, and likewise the small intestines. The great seat of the disease, however, is the colon and the rectum. Besides marks of redness and congestion, there is occasionally superficial abrasion of the mucous membrane, and sometimes deep-seated ulceration and great distention.

After the chronic form of the disease in the same situations, viz. the colon and the rectum, we find great redness and ulceration, but we also find that effect so peculiar to chronic inflammation—great hypertrophy; such thickness as acute inflammation will not induce. There is great thickness of all the coats; the rugae are all greatly enlarged, so that the inner surface is exceedingly rugged, and you see shreds of lymph hanging upon it, sometimes of great length. Occasionally these changes are seen only in patches, and occasionally they are seen over a very great extent; and at the same time red patches are frequently seen in the small intestines. The colon has been found after this chronic form of the disease as much as a quarter of an inch in thickness. Minute abscesses, too, are seen in the substance of the intestines. On opening the glands you find them so very much enlarged, so much hypertrophied, that they look like so many warts.

Besides the morbid appearances just mentioned, it is not uncommon to find the liver in a state of disease, frequently in a state of chronic inflammation; occasionally, indeed, in a state of abscess. The spleen, sometimes, is in the same predicament; the liver, however, is much more frequently affected than the spleen.

Causes.—As to the causes of dysentery, all agree that it is continually produced by changes from heat to cold, and from cold to heat. The tendency to it is greatly increased by long-continued heat, and by fatigue; therefore in those countries where it is continually seen it frequently breaks out when the army has suffered to a great degree, or there has been a sudden vicissitude of temperature. A cold wet night, after an intensely hot day, will occasionally produce this affection in a vast number of persons. It is a disease particularly common on board ships and in camps. Some consider that one cause of it is malaria, and certainly it is a fact, that where malaria prevails to a great extent, dysentery is very common; but as these are wet situations, one hardly knows whether it is the malaria itself which gives

rise to it. You will recollect I mentioned that with the remittent fevers of hot countries there are bilious fevers of all kinds. It is also undoubtedly produced sometimes by bad food, and likewise by bad water. This disease, for example, prevailed in the Penitentiary at Milbank, where there is a combination of unfavourable circumstances. The prison itself is situated in the most unwholesome place imaginable, as if it were intended to carry the people off quickly who have been deposited there; and I believe the allowance of food was not such as medical men considered to be proper. It co-existed there with scurvy, and various other diseases.

Formerly prevalent in London.—Formerly dysentery was very common in London, but at present we seldom see it. I scarcely ever meet with a case but in those who have been in hot climates, whereas formerly it was one of the greatest scourges in the metropolis. You find it treated of by Sydenham as one of the diseases that came daily under his observation: it was one of the great causes of mortality in the city, just as was the case with ague, plague, and scurvy. I presume it arose, then, from the bad quality of the food upon which people lived, and the bad drainage of the city. As to the ill effect of bad water, it is said that those in ships suffer most, when the disease prevails, who are nearest the pump.

Influence of Fruit.—It has been supposed that fruit produces the disease, but unless the fruit be bad, there is no reason to suppose that this is the case. Of course bad fruit, coming under the head of bad food, might produce it, but the mere circumstance of eating fruit at the time when nature provides it for us, does not give rise to the disease; on the contrary, there are many cases on record of fruit having proved exceedingly beneficial. You will find it mentioned by Zimmerman, in his work on Experience, which is well worth reading, for it is as amusing as a novel, and full of instruction, that in 1751, a whole French regiment was nearly destroyed in the south of France by dysentery. The officers purchased the entire crop of several acres of vineyard for the regiment, and not one man died from that time, nor was one more attacked. Tissot, a French writer, also mentions that eleven persons in one house were attacked with dysentery: nine of them eat fruit and recovered, but the grandmother and one darling little grandchild had wine and spices instead, as being the most comfortable thing, and both died. It was observed that the worst flux which was ever known in the army in Holland occurred at the end of July, when there is no fruit there

but strawberries, of which the men never partook, and the disease ceased entirely when October arrived, and the grapes came, of which the men eat very heartily.

Impure Water.—Any cause of intestinal irritation may, of course, produce dysentery, more particularly when a predisposition has been given by long-continued heat and by bad food, under which, of course, drink is included. It is said that at the old barracks at Cork the troops had water contaminated by the common sewers, and made brackish by the tide, and dysentery prevailed. This was remedied, and the disease almost entirely ceased. Linneus's friend, Rolander, had dysentery from drinking standing water out of a cistern of juniper wood. He ascribed the disease to animalculæ, but the mere circumstance of its being stagnated water, was sufficient to account for the disease, without calling in the aid of animalculæ.

Contagious nature doubtful.—It was formerly supposed that this disease was decidedly contagious, and it was imagined that it spread most from the stools; so that if any individual followed another labouring under dysentery, for the purposes of nature, it was conceived that he was more liable to catch it than by simply being with him. Whether it is contagious or not, it is impossible for me to say, but the sporadic cases of chronic dysentery, which we occasionally meet with in those who have come from hot climates, certainly are not contagious. I never saw any thing that could lead to the supposition of the disease being so. I will not presume to deny that sometimes it may be so abroad, but many diseases are supposed to be contagious that are not. I think it may be reasonably doubted whether it is contagious. Some imagine that almost any particular disease, under particular circumstances, may become contagious, and therefore I do not say that it never is contagious, but as the disease is seen in England, certainly it is not.

Mortality in the Peninsular War.—I mentioned that this was a disease which prevailed particularly in camps, and in the fleets abroad. In the Peninsular war our army lost no fewer than 4717 men by this disease exclusively. In 1812, 2340 died; in 1813, 1629; and in 1814, 748.

The disease is very manageable if taken in the first instance, but extreme mortality arises from the unfavourable circumstances in which men are placed. From the want of all comfort and the excessive fatigue, medical men have little chance of doing good.

Pathology.—With regard to the nature of the disease, it appears to be inflammation of the mucous membrane, together

with spasm of the muscular fibres, *chiefly* affecting the large intestines—one ought not to say altogether, but infinitely more frequent than the small intestines. The inflammation gives rise to constant pain, to sickness, to pyrexia, to a great discharge of mucus and blood; the spasm gives rise to occasional severe pain, and to the retention of the feces.

Prognosis.—As to the prognosis of the disease, that must depend, of course, upon the violence of the symptoms; but you will always find it mentioned in authors that one of the worst symptoms that can occur is the discharge of worms, as though the worms instinctively knew that the habitation was about to be dissolved, and therefore the sooner they quitted it the better, just as rats are said to quit an old barn, and look out for a new habitation before they are turned loose by the destruction of the present.

Treatment.—In regard to the cure of the affection, the first thing is, to remove, if possible, the cause of the disease. If there be a bad quality of the ingesta, whether liquid or solid, or any dampness in the situation, or any contamination of the atmosphere, all this should be obviated either by removing the patient from it, or it from the patient, otherwise you are fighting, of course, against a double enemy—both the disease and the cause.

In acute dysentery we have to treat the affection upon a decidedly antiphlogistic plan. It may be necessary to bleed vigorously in the arm; to apply leeches freely and repeatedly to the abdomen; to give mercury, and get the mouth sore; to apply cataplasms of hot moist bran to the abdomen, or if it be preferable, apply them cold, but in general the moisture answers much better if it be warm. You must treat it as a violent active inflammation of the intestines. In regard to calomel, you will find, that though all agree upon its importance in this disease, yet that some recommend large doses at intervals, and some small ones. Those who recommend the latter would give other purgatives at intervals, for the purpose of emptying the intestines, such as castor oil; whereas, those that give large doses, trust more to the calomel itself. It is highly necessary in this disease to open the bowels well. Notwithstanding the number of evacuations, the feces are altogether or greatly retained, and therefore it is necessary not merely to employ the remedies for inflammation, but to empty the intestines thoroughly. Some people would give a scruple of calomel at intervals, so as to get the mouth sore as quickly as possible, and at the same time to empty the alimentary canal. Those who give

small doses would give other purgatives in great abundance; but it is necessary to get the bowels open as speedily and as effectually as possible. It is useful to employ opium at the same time, on account of the great tendency which there is to severe spasmodic pain. The opium may be united with the calomel; and if you take care to make the calomel operate by means of other purgatives, no harm can arise from it. If castor oil will stay on the stomach, I should prefer that to salts, because, perhaps, there is a great discharge of mucus, and perhaps watery stools rather than feces, and castor-oil has the property of thoroughly emptying the alimentary canal. Emollient clysters are also of the very highest importance, but nothing acrid should be put into them. Clysters of gruel, with a certain portion of laudanum and castor oil, will be much better than clysters containing salts. Of course the patient should be kept without food; his stomach should be allowed as much repose as possible; he should be kept exceedingly low.

Many persons, formerly at least, had a very high opinion of ipecacuanha in this disease. Dr. Akenside, the poet, in his elegant Latin treatise on this disease, recommends about three or five grains of ipecacuanha every six hours, and many persons still give it, and also antimony, so as to create sickness. I myself have no experience of any such plan. I do not see the utility of causing the patient to vomit in this disease, neither have I ever myself been able to discover the soothing effects of ipecacuanha. Some persons when they give purgatives give ipecacuanha, and say that it has the property of emptying the alimentary canal; but after repeated trials, I cannot say that I have found that it has any peculiar properties except that it makes the patient sick. I have been as successful in this disease as in any other by treating it on antiphlogistic principles, without exhibiting any thing with the view of producing sickness or any specific operation. Formerly various preparations of antimony were given, but I really myself have not found it at all necessary.

In regard to the chronic form of the disease, you are to consider whether there is any inflammation still existing. There very frequently is; the abdomen is still tender, and it would be absurd to think of giving astringents, and blocking up the intestines, while that inflammation exists. You will find that the readiest way of lessening the disease is, in the first instance, to apply leeches freely over the abdomen, and throw up a clyster, taking care that the bowels shall be opened freely and regularly; and when you have done all this, then astringents will be very proper.

In chronic dysentery there frequently is no inflammation at all; the time arrives when there is a mere gleet of the surface, or the surface is merely in a state of irritation, and in that condition opium and astringents of all kinds are exceedingly serviceable; but you may do infinite mischief unless you ascertain before you give astringents that there is no inflammation. If there be inflammation, you must treat it accordingly, by leeches, blisters, fomentations, and things of that description, and you must take care to see that the bowels are regularly opened and the fæces discharged, because if there be no inflammation at all, and the fæces are not discharged, and you exhibit astringents, you will produce inflammation, though there was none at first. But in the chronic form of the disease, the fæces are at last discharged pretty well, and no purgatives are required; still, however, the character of the acute disease so far remains that there are bloody and mucous stools, a desire to go to stool, and tenesmus.

In this form of the disease astringents may be given safely, and may be either vegetable or mineral; and it is best to combine them with opium. By far the best astringents that I know, are kino and catechu. It may be right not to give the tinctures, as they may excite the pulse and irritate the patient; but to give them in an infusion. Opium is very much required in this disease, to prevent griping. As I before said, opium is often very safe and very useful in the acute form of the disease, provided you take care to subdue inflammation and keep the bowels open; but in the chronic form it may be given with very great safety, provided the bowels be regularly open, as is usually the case. A good mode of exhibiting the opium is to give *pulvis catechu compositus*: it will not irritate so much as opium itself will do.

You will find that when the ordinary astringents (catechu and kino) fail, mineral astringents will frequently cure the disease; and that which I have been most in the habit of employing, and with very great success, is the sulphate of copper. The way in which I became acquainted with its use was from hearing a gentleman state that at the Medical Society, at Guy's Hospital, a case had been read of violent chronic diarrhoea, which yielded to nothing but copper. Dr. Sutton, of Greenwich, informed me at a consultation the other day, that he had a very obstinate case, and all astringents having failed, it occurred to him to try this, and he did so with very great success. I have consequently used it, and it certainly is one of the best where mineral astringents are required; but it is necessary to remember that you should not

give it on an empty stomach, because, if it come in contact with the organ, it will excite vomiting. It should not be given till after breakfast, and that is the case with most acrid substances. It stands to reason, that if they be not given till the patient has had a meal, they will produce less irritation of the stomach than if they come in direct contact with it; which they must do when the stomach is empty. It is right to give this medicine in the form of a pill, because all acrid substances act more powerfully if they be in a state of solution. If it be given in a pill, it comes in contact with a smaller surface, and will therefore produce less irritation than if it be diffused. It is generally right also to give it with opium, because, although it is an astringent, yet it is an acrid substance. It has two properties—the one astringent, the other acrimonious—and therefore it is best united with opium; but I have frequently omitted the latter and continued the former, with perfect safety. The smallest dose which it is worth while to exhibit, is a quarter of a grain; and you may gradually increase this to three grains. You may consider this the largest dose that patients will ordinarily bear; in fact, many will not bear more than a grain and a half. It produces no constitutional effect: I have known a patient take it for three years, for a peculiar kind of diarrhoea, without any such result. I never saw such a constitutional effect arise from it as occurs from lead or arsenic, or any other mineral substance. If it produce sickness, you will find it of great use to give hydrocyanic acid with it. If you give from one to four drops of the acid, according to the necessity of the case, when the copper is taken, you will find that patients will bear it without sickness and without nausea, though, perhaps, without it there would be both. By a steady perseverance with this, or vegetable astringents and opium, taking care at the same time to have the abdomen well covered with flannel—making the patient avoid cold, and all sorts of ingesta likely to irritate the alimentary canal, and at the same time supporting his strength—you will effect a cure in the greater number of cases. It is a rare thing for me to lose a case of dysentery; I do not know how long it is since I lost one, but certainly it is not a very common complaint.

In the chronic form, if the intestines be ulcerated, you may still cure the disease; for it is only when there is a very great degree of ulceration that patients die from it. Ulceration of the intestines will heal just like ulceration of any other part; but of course you will meet with cases where medicine can do no good—where the in-

testines are in a state of hypertrophy, look as if they were worm-eaten—where the mesenteric glands are diseased, and frequently perforation takes place, and the patient is destroyed by peritonitis. A representation of such a case as this is presented in Dr. Baillie's plates, and nothing can be expected to do any good in it. A surgeon would not be expected to cure a leg or an arm in such a state as that. If the patient may sink from such a disease of a part so unessential to life as an extremity, much more may he do so in the case of the intestines. Some persons in this affection recommend other substances—such as nitric acid and muriatic acid, united with opium and astringents; but, *à priori*, you would expect that such medicines would only cause irritation. However, there is testimony in favour of muriatic acid combined with opium, and some say nitrous acid. I have never given acids in the disease: I have known them, when taken in other diseases, produce a pinching in the bowels, and therefore I have never ventured to give them to a patient labouring under this affection.

You will find it very necessary to alleviate one symptom, and that is the tenesmus. If there be any tenderness about the abdomen at large, leeches should be applied to the anus as well as to the front of the abdomen; because tenesmus may arise from an inflammatory state. When, however, it does not arise from an inflammatory state, but rather from irritation than any thing else, opium is very useful. It is best to give it in the form of tincture, in a very small quantity of fluid. About four ounces of fluid is the utmost that can be given, because you wish it to be retained, and not to be rejected. Bulk will irritate as well as acrimony, and, therefore, when you are giving it to lessen the pain and tenesmus, as small a quantity as possible should be employed. About forty or fifty drops of laudanum, given in a little starch, is one of the best injections of the kind. Sir James McGrigor says, that, in the Peninsula, he found great relief from injections of acetate of lead; so that we might put laudanum into a solution of the acetate of lead: I presume one or two grains of the latter would be enough. We know that lead has a soothing effect on a raw surface, or on a mucous surface in general, and therefore we can conceive that this would be a proper medicine.

As to mercury, in the chronic form of the disease I have never given it: I have always been able to cure the affection, as we see it in this country, without it; and Sir James McGrigor says, that in the Peninsula it was worse than useless—it was absolutely injurious, unless the liver was

diseased at the same time. I have repeatedly watched the motions in this disease; in scores and scores of cases they were quite white, and white for a month or two, more like paste than any thing else; and, without giving any mercury, I have suddenly seen bile in them. The intestines are restored to their function, the health is improved, the liver begins to do its duty properly, and, without exhibiting mercury, you will see the bile return, sometimes gradually and sometimes suddenly. When you consider that mercury renders the body more susceptible of cold, and that your object is to soothe the patient, I would not recommend it to be given in the chronic form of the disease.

I believe I mentioned the necessity, in the chronic form of the disease, of well bandaging the patient's abdomen; and some persons, instead of employing flannel, prefer straps of adhesive plaster all over the loins. This might be applied first, and bandages over it.

ON

FACIAL PALSY AND ANÆSTHESIA.

FROM A

Lecture lately given at the Middlesex Hospital.

BY DR. WATSON.

GENTLEMEN,—During the last few months instances of disease, affecting one or both of the two primary functions of various parts of the nervous system, have been unusually numerous in our wards; the functions, I mean, of cutaneous sensation, and of motion in the voluntary muscles. To the student who witnesses such cases, the instruction they convey should increase in proportion to their number, which admits of their being collected into one general view, compared one with another, and estimated in relation to various circumstances, some common to all such diseases, others occasional only, and giving to the case in which they occur its peculiar character and chief importance. All diseases of this kind, whatever be their degree or extent, are distressful and alarming to the patient. Some of them indeed are, in reality, merely inconvenient or disfiguring; many, however, have a more serious import, and bespeak a condition of extreme danger to the sufferer; others, again, independently of their relation to the probable continuance of life, are especially calculated to elucidate some of the most curious and interesting speculations of modern

physiology. I propose, therefore, to take a summary view of these cases in the present lecture, recalling to your recollection their principal points, going into detail with respect to a few, and tracing the outline only of others, where a fuller account would be mere repetition, or irrelative to my immediate purpose.

The abolition or diminution of the power of voluntary motion, and the abolition or diminution of the faculty of sensation, often occur together; and, accordingly, both of these morbid states used to be expressed, and are still frequently expressed, by the same general term, "paralysis." But each may exist without the other; and it is more convenient, especially since the discovery that the two functions in question belong to distinct portions of the nervous system, that different terms should be employed to signify their diseased conditions. Whenever, therefore, to avoid circumlocution, I use the word *paralysis*, or the English derivative *palsy*, you will understand that I intend a loss of power over some of the voluntary muscles; and when I wish to express loss of sensation, you must not think me pedantic if I call it *anæsthesia*. We have no English word for this affection. *Numbness* comes the nearest to it, but it is not exact, or, at best, it signifies a degree only of *anæsthesia*.

There are certain voluntary muscles, or sets of muscles, of which (I say) the palsy is, sometimes at least, a mere inconvenience or deformity. We see this in some instances of paralysis of the face, of which I shall say more presently; and in the case (and of this kind also we have had several examples before us of late) of palsy of the extensor muscles of the wrists, produced by the poison of lead. On the other hand, instant and inevitable death is the effect of the palsy of certain other sets of muscles; those concerned in the acts of respiration, for example. These muscles are paralyzed at once by the division of the spinal marrow high up in the neck, and the consequence is immediate suffocation. Of course the same event would follow *general* palsy—a loss of power over *all* the voluntary muscles; so that every case of palsy, of sufficient duration to submit itself to medical treatment, must be *partial*—must be confined to certain muscles, or sets of muscles, only. Hence we may conveniently classify some of these complaints according to the muscles that are involved—according, *i. e.*, to the visible effects of the interruption of the nervous function; and then endeavour to trace the disease to its source in some part of the nerve itself supplying those muscles, or of the brain or spinal cord with which it communicates.

Now there is a very remarkable set of cases in which the muscles of one side of the face are exclusively the subject of palsy. The appearance presented by a patient under these circumstances is peculiar, and very striking. From one half of the countenance all power of expression is gone; the features are blank, motionless, and unmeaning. The other half meanwhile retains its natural cast, except that, in some cases, the angle of the mouth on that side seems drawn somewhat awry. This is apt to be mistaken for proof of a spasmodic condition of that part; but it is owing simply to the want of the usual balance or counterpoise from the corresponding muscular fibres of the palsied side. The patient cannot laugh, or weep, or frown, or express any feeling or emotion with one side of his face, whilst the features of the other may be in full play; and from this incongruity his aspect would be ludicrous, if it were not so seriously distressing. Indeed, we find that with persons who do not comprehend the possible extent of the misfortune they are contemplating, the strange appearance of such a patient is always a subject of merriment; on the other hand, his friends and relations imagine he has had a fit, and are in great alarm for his life. In the majority of these cases there is not, however, any real danger of that kind to be apprehended—a circumstance which, of itself, would render the exact diagnosis of the complaint peculiarly interesting. There is now, in Bird's ward, under Mr. Mayo's care, a patient in whom you may examine for yourselves the effects of this singular malady upon the movements and character of the countenance. This woman fell—I believe she threw herself—from a window into the street, and, lighting upon her head, fractured both the zygoma and the jaw-bone of the right side; and another consequence of the injury has been the paralysis of which I am speaking. But you may perhaps suppose that, in this instance, the muscles themselves have been so much bruised and hurt, as to be for that reason incapable of contraction. I will therefore take a simpler case, uncomplicated with any outward injury, in illustration of the phenomena which such paralysis occasions.

A housemaid, Jane Smith by name, 28 years old, presented herself here as an out-patient, with the following symptoms. She had lost all power of moving the right side of her face. When she endeavoured to raise her eye-brows, the right side of the forehead remained smooth, and the left was wrinkled. When she attempted to close her eyes, the right eye was but partially covered, the eyeball rolling upwards, and carrying the cornea within the curtain

of the upper lid, which descended a little to meet it. When she smiled, the right side of the face remained immovable, and it wore at all times a blank and expressionless character. When she was told to perform the action of blowing, the right cheek was pulled out like a loose bag, and the breath issued, whether she would or no, at the right angle of her mouth. The same thing happened with her food and drink: she could not prevent their escaping at the right corner of her mouth, nor could she convey morsels of food from the right to the left cheek without the aid of her hand applied externally in support of the paralysed cheek. The masseter and temporal muscles acted, however, as strongly on the one side as on the other; and the sensation of the palsied parts remained perfect. There was no paralysis of any other part of the body.

All these phenomena are invariably met with in all cases of this kind. Whilst they are fresh in our recollection, let us contrast them with those presented by another of our patients, Ann Church, who lies in King's ward. The symptoms for which this woman sought admission into the hospital were intense pain, with some swelling, of the right temple, and extending generally over the right side of the face and head. It was soon discovered, however, that although she complained of most severe pain in these parts, they had entirely lost their ordinary sensibility to external impressions. She felt nothing when her forehead, or cheek, or nose, or chin, was touched on that side. In short, there was complete anæsthesia of the right half of the face, the insensibility being very exactly limited to the right half, and terminating abruptly at the mesial line. It was remarkably evident in a part with respect to which we could not be deceived, even if there had been any reason (which there was not) for suspecting the truth of the patient's statement. The surface of the eye-ball is proverbially sensitive, especially to slight impressions. But you might place your finger upon this woman's right eye, or you might brush it with a feather, without giving her the smallest pain, or producing any sensation at all; whereas, on the left side, the lightest touch caused involuntary shrinking, and closure of the eyelids, and lachrymation. She declared also that she had no feeling in the right half of her mouth; she neither tasted sapid substances, nor was at all conscious, from any sensation produced by them, that they were placed there. Her lips on the same side were equally destitute of sensibility; so that when she drank, having no perception of the contact of the cup with her lips beyond their middle point, she felt as

if she were drinking from a broken vessel. This is a circumstance which all persons who are thus affected are much struck with, and it almost always forms a part of their voluntary history.

Besides this default of sensibility, the power of contracting the masseter and temporal muscles was entirely abolished. You will recollect that it remained perfect in the former case. You may deceive yourselves on this point if you do not examine it carefully, and with certain precautions. At least I have known persons doubt, because, having desired the patient to open and shut his mouth, they have confounded the movement of the whole jaw with the action of the masseter muscle. But if you direct the patient to close the mouth, and then to perform the action of grinding his teeth, placing your fingers at the same time on the corresponding muscles on each side, the difference, when it exists, will be very striking. In this woman, no swelling of the masseter or temporal muscle on the affected side, took place when she forcibly closed her jaws. There was no other paralysis. Some difficulty in the movements of the face on that side existed, it is true, on her admission; but this depended wholly upon the swollen state of her cheek and jaw, and disappeared as the swelling subsided. At all times she was able to depress, or draw backwards, the angle of the mouth on that side.

Now the morbid conditions, of which the two cases just described are samples, illustrate, in a very beautiful manner, the modern doctrine respecting the special uses of particular nerves. In the former of the two cases, the palsy resulted from an interruption of the function of the hard portion of the seventh pair of cerebral nerves; and the anæsthesia, in the latter case, depended upon an interruption of the function of the fifth pair. You know that experiments performed upon living animals have proved that the division of the *portio dura*, before it spreads out into that remarkable nervous net-work on the side of the face, paralyzes all the muscles, the combined play of which gives variety and significance to the countenance; and that, on the other hand, the division of the fifth nerve deprives the same parts of their sensibility. In these two cases, and in such as these—for they are by no means unfrequent—a similar set of experiments upon the same nerves in the *human* body is performed before our eyes by the agency of disease or accident; and the result justifies most completely those conclusions which had been deduced, in the first instance, from contrived observations made upon the lower animals.

I feel a peculiar satisfaction—as a colleague of that distinguished Physiologist by whose genius and sagacity the modern theory of the nerves was first unfolded—in pointing out to you, in this place, these striking confirmations of its truth and usefulness.

There is one point in the history of these cases upon which I must dwell a moment longer, for it appears to me extremely interesting. That the condition of the masseter and temporal muscles should be reversed in two patients so oppositely situated, was no more than might have been expected; but, in each, these muscles were affected in a manner the very contrary of that which the general circumstances of the case would, *a priori*, have prepared us to anticipate. Where the superficial muscles were paralyzed, and the principal movements of the face suspended, there the masseter and temporal muscles were in full action; and where the loss of sensation was the prominent phenomenon, and the ordinary motion and expression of the countenance remained, there these muscles were in a state of complete palsy.

A few years ago, this difference and apparent inconsistency would have been quite inexplicable. The progress of modern science has removed the difficulty, by establishing a general agreement between the functions of different nerves, and certain observed peculiarities in their anatomical relations and arrangements.

Suffer me to remind you (for I am aware that these things are now taught in all our schools of physiology) that the nerves which proceed from the spinal column on each side, are connected with it by two fasciuli of nervous fibrils—two *roots*, as they are called—of unequal size; that when the larger of these, which is situated posteriorly and is furnished with a ganglion, is divided in a living animal, the parts to which the nerve is distributed lose the faculty of sensation, while the power of voluntary motion remains unimpaired; that when the smaller and anterior, which has no ganglion, is alone cut, the same parts are instantly paralyzed, but retain their sensibility.

Now the fifth pair of cerebral nerves was observed to have a similar origin—to be composed, that is to say, of two fasciuli or roots, one larger than the other, and invested with a ganglion; the other smaller, and having no ganglion. It was naturally inferred that the functions of these roots would be analogous to those of the corresponding portions of the spinal nerves—that the ganglionic fasciculus would relate to sensation, and the other to motion—and such is found to be the case; and the arrangement here is really very curious. The smaller portion of the fifth nerve is

exclusively expended upon a very few muscles—viz. the masseter, the temporal, the two pterygoid muscles, the circumflexus palati, and the tensor tympani. The action of the two first of these is obvious to common observation, and therefore their condition is noticed in the patients whose cases I have related. Again: these very same muscles have been shewn, by careful dissection, to receive no nervous branches from the seventh nerve, which ramifies so abundantly upon the superficial muscles of the face.

It was to be expected, therefore, that any affection confined to the portio dura of the seventh nerve, would leave these muscles (the temporal and the masseter) in action; and that disease involving the fifth nerve, but leaving the seventh unaffected, would destroy, not only the general sensibility of the face on that side, but also the power of contraction in these particular muscles; and you perceive how beautifully this is exemplified in our patients. Smith had total palsy of the superficial muscles, but sensation, and the action of the deeper-seated muscles, continued perfect; while in Church, there was default of sensibility and paralysis of the temporal and masseter muscles, but the movements of the superficial muscles were unimpeded.

Every interruption of the function of the portio dura will paralyze these superficial muscles of the face; and such interruption may be occasioned either by sudden injury done to the trunk of the nerve, or by disease affecting its proper structure, or by pressure, the consequence of disease in the parts contiguous to it: and it is important to observe that the morbid condition which causes the interruption may be situated in any part of the course of the trunk of the nerve: while it is yet within the cranium; or during its passage through the petrous portion of the temporal bone; or after it emerges upon the face through the stylo-mastoid foramen, to be ultimately spread in meshes over the face, and temple. The nerve is often compressed while still within the skull; but in *most* cases of this kind, other portions also of the nervous matter are involved in the mischief, and other sets of involuntary muscles testify this by their immobility or their irregular action. When the facial muscles alone are paralyzed, it happens, in a great majority of instances, that the nervous function is interrupted either in that portion of the nerve which lies incased in the bone, or in the more exposed part which issues in front of the ear: and hence it is that this particular form of palsy is, *in general*, unattended with any danger to life.

The proximate cause of this remarkable species of palsy, and the true explanation

of its prevailing immunity from danger, were first pointed out by Sir Charles Bell; but both the existence of the malady, as a distinct form of disease, and its comparative harmlessness of character, had been observed and described some years previously, although the reason, neither of the one nor of the other, was at that time known. Dr. Powell has narrated, in the fifth volume of the *Transactions of the College of Physicians*, three well-marked instances of this form of partial palsy, and has noticed, at the same time, its apparent independance of any apoplectic tendency, or cerebral disease.

The exciting causes of this complaint are many and various. Sometimes it is the consequence of mechanical violence, by which it is plain that the nerve has been lacerated, or otherwise injured. Sir Charles Bell, to whom we are indebted for all our useful knowledge on the subject, mentions several examples of this kind. In one, a man was shot by a pistol-ball, which entered the ear and tore the portio dura across at its root; in another, the patient was gored by an ox—the horn of the animal entered beneath the angle of the jaw and came out in front of the ear, tearing the nerve across; in a third, the nerve was divided by the scalpel, in an operation for the removal of a tumor which lay above and around its course. In all these cases the injury was external and obvious. In a fourth, the palsy followed a blow on the ear, which caused hæmorrhage from that part: here, probably, the nerve was hurt in its passage through the bone. Some time ago, a man was brought into the hospital who had fallen from a height upon his head: the muscles of the left side of the face were paralyzed. He died in a few days, and examination of the head shewed a fracture of the base of the skull, passing through the petrous portion of the left temporal bone, and rending the seventh pair of nerves at its entrance into the meatus auditorius internus. Some of you will recollect one of my patients (Richard Hills), who was in Pepy's Ward about this time last year: in him the same kind of paralysis seemed to have been occasioned by a mere shock, or jar. He was a coachman; and one day, when he was off his box, his horses started away, and he ran to their heads to stop them, but was thrown down in the attempt, striking his right hip and elbow. He received no blow on the head at all. Three hours afterwards, he found that he could not spit properly—that he could not avoid spitting on his clothes on one side, and that he could not whistle. Another circumstance worthy of notice took place in this man; which often, though not always, happens in these cases, and which I did not mention before. He remained

for about two months in the hospital, and regained during that time, in some degree, the power of exercising the affected muscles; but he still was unable to close the right eyelids. The eye itself was unharmed. After he was made out-patient, he resumed his functions on the coach-box, and his eye, permanently half open, was more exposed to cold and currents of wind than it had been while he was here. Moreover, he got drunk; and he soon presented himself again, with universal redness and inflammation of the conjunctiva. You may see the same effect of the inability to close the eyelids in Mr. Mayo's patient, now in the house. Sometimes the inflammation produces opacity of the cornea and a total loss of vision. This is one of the worst consequences of the palsy; it is, however, only an occasional consequence, and it will occur or not, according to the quantity of motion which remains to the eyelids—the degree of exposure to the ordinary causes of inflammation—and (it may be) the peculiar susceptibility of the patient.

Sometimes the palsy depends upon manifest external disease; sometimes upon disease which is hidden, and probably internal; in the bony canal. Sir Charles Bell describes an instance in which it accompanied cynanche parotidea. Dr. Mahlen, of Worcester, witnessed another, in which a fixed, hard, indolent tumor, had formed between the ramus of the lower jaw and the mastoid process of the temporal bone: as this tumor gradually subsided the palsy disappeared. In each of Dr. Powell's three cases, the affection was apparently caused by exposure of the side of the head, for some time, to a stream of cold air. The same cause operated upon a Scotch physician, as he was travelling to London by a coach, and sent him, in great alarm, to Sir Charles Bell. Three years ago, a marked example of facial palsy presented itself in one of my patients, in whom it appeared to be owing to his having been constantly in the streets for some days, in a very miserable condition, without shoes or stockings, during a cold thaw. It may be presumed, that in these instances some swelling was produced in the soft parts around the nerve, compressing it where it lies within the unyielding bone. Cases of this kind are more obedient to treatment than most others. There are still other cases in which we fail to discover any direct explanation of the paralysis, either in the history of the patient or in his physical condition. In Jane Smith, whose symptoms I stated in detail, as an example of the appearances uniformly present, the malady came on without any obvious cause, and has resisted all the means employed for its removal.

That the greater number of cases of this kind are free from serious peril, is a fact of great practical importance. It enables us to quiet the alarm of the patient and his friends, and regulates, in many instances, the treatment—rendering it less rigorous than it might and should be if the palsy were really the harbinger of apoplexy. At the same time you ought to know that a similar limitation of paralysis to the particular muscles supplied by the portio dura, is sometimes (though rarely) observed, when the disease has a more inward origin—when it affects and involves the brain itself.

In the latter end of September, in the year 1829, a gentleman became my patient in whom complete palsy of the left side of the face had existed for a day or two. I need not describe the appearance and symptoms which depended upon the paralysis, for they were precisely the same as were presented by Jane Smith, and they are always, and necessarily, very much alike. But though the *palsy* was strictly limited to this set of muscles, there were other symptoms present which indicated that the interruption of the function of the portio dura was connected with some morbid condition within the cranium—nausea and vomiting, twitchings of the muscles of the *other* side of the face, great drowsiness, and a slow pulse, forty-eight only in the minute; he lurched also, and staggered as he walked; but he distinguished this from the reeling of vertigo, and denied the latter sensation altogether. His previous history did not tend to diminish the fears which his actual state occasioned.

In the preceding February he had been attacked rather suddenly with intense pain just above the right eyebrow, and became extremely drowsy. Being desirous to excuse himself from a dinner engagement, he found that he was unable to write a proper note: he could not remember how he ought to express himself.

He had another attack of the same kind in May—the same severe pain over the right brow, with great drowsiness and confusion of mind. He could not recollect many familiar words. On both these occasions the symptoms soon gave way to treatment directed to the stomach and bowels.

Cupping behind the ear, blistering, purgatives, and small doses of calomel continued till the gums were slightly sore, removed the paralysis, and all the other symptoms, in about ten days, and he is now in perfect health.

But you have lately seen an unequivocal example of the same combination of internal disease with palsy confined to the muscles that are governed by the portio

dura, in the person of Samuel Dorey. This man, a tailor, aged 57, was admitted into the hospital, on the 26th of February last, with complete palsy of the muscles supplied by the nerve in question on the right side, and of no others. There were symptoms enough, however, to shew that some serious morbid process was going on within the skull. He suffered intense headache, more on the left than the right side; was dizzy and staggering, and could not get to the ward without being led.

The palsy had come on about ten days before, in the night. He found when he came down stairs the next morning that he could not spit as usual, and his friends observed the unnatural state of his features. He had had no fit nor loss of consciousness, but he fancied that his memory was failing. At the time when the paralysis was first noticed he had some numbness and tingling of the right arm, extending to the two last fingers. He was quite deaf in the right ear.

I had him cupped, cold lotions were applied to his head, and his gums were made tender by calomel. In a few days the pain in the head increased, and he became affected with drowsiness, approaching to stupor. He was then bled. The coma went off soon after the bleeding, but was succeeded by violent delirium; and this again subsided after free purgation. He began occasionally to pass his stools in bed, and unconsciously. On the 16th of March he again fell suddenly into a state of stupor. You saw him at that time, breathing stertorously, his lips flapping to and fro with each act of respiration, his face and head red, hot, and turgid, the temporal arteries distended and throbbing. I should have stated that at all times there was a sharp and peculiar bruit accompanying the contractions of the ventricles of the heart; the sound much resembled that made by drawing the finger forcibly along a piece of stretched silk. The temporal artery was opened at once, and about sixteen ounces of blood flowed freely in strong jets; the pulse then became feeble; the turgidness of the countenance subsided; and the blood just continued to well out, but the stertor remained. In a few hours, however, he was much better, and became sensible; the palsy was unaltered. The arterial blood was covered with a thin but distinct buffy coat. He lived till the 29th, being for the most part drowsy, sometimes completely comatose, but generally capable of being roused, and answering rationally when spoken to. For some days before his death it was observed that his arms were constantly bent upon his breast, and that whenever they were forcibly extended, they returned immediately to the

same position, apparently without any exercise of volition on his part, as soon as the extending force was withdrawn.

We examined his body on the 30th, thirteen hours after death.

The thorax was first opened. The lungs were healthy; the pericardium contained some serous fluid, tinged with blood; the heart was large, and encumbered with fat, its right cavities nearly natural; the left ventricle large, and its muscular substance thickened; the mitral valve also was irregularly thickened, but there was no manifest constriction of the corresponding orifice; the sigmoid valves stiff, and thickened; the inner surface of the aorta rough with disease in several places. Just within the ventricle a morbid appearance presented itself such as I had never seen before. A white prominent line, feeling to the finger like a sharp cord, ran along the interior of the ventricle, parallel to, and about a quarter of an inch from, the circumference of the emerging aorta. Upon closing the divided ventricle, it became plain that at this part of the chamber there had been a real stricture. The peculiar morbid sound which accompanied the ventricular systole during life depended perhaps upon this contraction; and I would suggest, as a mere conjecture, however, that the contraction itself, or rather the projecting ridge that caused it, might have arisen from some altered action of the diseased mitral valve, with the insertion of which the line of stricture was continuous.

But it is to the examination of the head that I chiefly wish to recal your attention at present. When the skull-cap and dura mater had been removed, you saw that the surface of the brain was quite dry and flat; the sulci, between the several convolutions were scarcely apparent. Whenever you meet with this dry and level condition of the surface, you may be sure of finding some cause of pressure within. Accordingly, the left lateral ventricle was enormously distended with clear serum, and remained of a vast size when emptied, while the walls of the ventricle on the right side were forced into close apposition by the pressure of a tumor which occupied a large portion of that hemisphere, the central part of the tumor being rather posterior to the centre of the hemisphere. The posterior portion of the tumor was of a red colour, and soft; centrally it had a light orange tint, and a spongy or cellular structure, and its anterior part was hard, homogeneous, and pearly in appearance. The tumor was about three inches in length, nearly two in breadth, and of considerable thickness. By a subsequent section, an apoplectic clot, as big as a hazel-nut, was discovered at its under part. I presume

that this was the result of the rupture of some small vessel in the progress of the disease, and that the effusion of blood took place at the period of the deep coma on the 16th. The arteries at the base of the brain were partially thickened, the thickened portions being white, opaque, and dilated.

The further prosecution of the dissection afforded a most satisfactory explanation of the deafness and the partial palsy which had been noticed during the life-time of the patient. The portio dura, and the portio mollis, where they emerge as distinct cords from the medulla oblongata on the right side, were adherent to each other; the portio dura was both harder and larger than the corresponding nerve of the opposite side, while the portio mollis was diffuent and wasted. The same change was traced to their entrance into the petrous portion of the temporal bone. Immediately over the medulla oblongata, and in a vertical line above the point of emergence of the seventh pair of nerves, a nipple-like portion of brain projected downwards, and had apparently communicated pressure to these nerves; and this projection from the lower surface of the brain seemed to have been produced by the general pressure resulting from the growth of the tumor.

The remarks which I have been applying to *palsy* of these parts, hold true also in respect to their *loss of sensibility*. The anæsthesia may, or may not portend danger to life, according as the interruption of nervous function on which it depends is situated more or less near to the origin of the fifth pair of nerves in the brain. The insensibility was beginning to yield, and the pain had very much abated in our patient, Church, after cupping and leeches on the temple, when erysipelas came on, spreading, apparently from a blistered surface behind the ear, all over the right side of the face and head, and afterwards extending down the neck. With this there ensued much fever and delirium, and I began to be anxious about the event. Until this accidental supervention of erysipelas, there were no symptoms present that indicated any positive affection of the brain or its functions. She is now, I think, out of danger, but very feeble, and teased by abscesses in the cellular tissue of the eyelids and neck, but she has regained a considerable degree of sensibility in the parts that were before without feeling, although (which is curious) the palsy of the masseter and temporal muscles continues absolute*.

* Since the lecture was delivered, this patient has recovered in a great measure the use of these muscles. Her general health is quite restored, and the sensibility of the face is nearly as perfect as ever.

You may contrast this woman's condition with that of Wm. Godwin, (a man only 29 years old) who was for a short time in Stafford's ward, and who still presents himself here every week among the out-patients. The time will not permit me to go at large into his case, but I will just remind you, that besides a marked defect of sensibility in the left side of the face, exactly of the same kind, and affecting the very same parts as in the woman, only not so complete in degree, this man is unable to raise his left eyelid; the pupil of that eye is largely dilated, and immovable under the strongest light; and he has been gradually losing the full use and command of his *right* arm and leg. These *additional* symptoms teach us that the disease or injury which impedes the function of the fifth pair of nerves, affects other portions also of the nervous system, and is situated within the skull. I need not tell you how materially they diminish his chances of recovery, or of a long life.

Instances in which the paralysis of which I have been speaking was combined with palsy of other parts—was, in short, one of the symptoms of hemiplegia—have been numerous here beyond all precedent during the past winter, so as to lead some of you, I know, to inquire whether there has not been an *epidemic* hemiplegia. These cases would afford matter for some important remarks, but I must defer such observations as I may have to offer concerning them to another opportunity.

INSTRUMENT FOR TREATING FRACTURES OF THE JAW.

To the Editor of the Medical Gazette.

SIR,

I AM induced to send you the following description of an instrument for treating fractures of the jaw, from having found it useful in cases where the means usually employed had failed. Should you think it sufficiently important to deserve publication in your valuable journal, I shall feel obliged by your inserting it.

I remain, sir,

Your obedient servant,

EDWARD F. LONSDALE,
Lately House-Surgeon to the Middlesex
Hospital.

8, Berners-street, July 11, 1833.

Fracture at the symphysis of the lower jaw is an accident of rare occurrence, compared with that of other parts of the bone; and when it does occur, requires peculiar treatment, from the

great difficulty of keeping the two portions of bone in proper apposition. When the fracture exists on one side of the symphysis, or in the ramus, the difficulty of keeping the bones in proper apposition, though great, is still capable of being overcome by a very careful application of the means in general use; but when the symphysis itself is the seat of the fracture, there is an additional evil to contend with, viz. the action of the muscles that pass from the os hyoides to be inserted immediately within, and to one side of the symphysis of the bone. These muscles are, the digastricus, mylo-hyoideus, genio-hyoideus, and genio-hyoglossus, all of which are put into action during deglutition, and on the slightest motion of the tongue, and will consequently move the two portions of bones, either drawing them apart, or one below the other.

I found this very apparent in the case of an old man, admitted into the Middlesex Hospital last year, having fractured his jaw exactly at the symphysis. I tried the usual means, by inserting a piece of cork between the teeth, and firmly supporting the jaw with pasteboard and the four-tailed bandage. I also fastened the two middle incisor teeth together, by twisting strong wire round them. None of these means would keep the two portions of bone in apposition; the slightest act of deglutition put the muscles before-mentioned into action, and produced motion between the two portions of bone, either by separating them, or by drawing one below the other.

Finding all my attempts by the usual means to be of no avail, I contrived the following instrument, which only had a trial in this case sufficient to shew me that it was correct in its principle, and would ultimately succeed. I have since tried it on another case, and with perfect success.

The principle of the instrument is to keep the two portions of bone in a parallel line between two forces; the one made to act by pressing on the teeth, the other by pressing on the base of the jaw. A thin plate of iron is made to lie on the four incisor teeth, and grooved to fit on them in such a manner, that one portion of bone cannot be drawn behind the other; this plate is connected with a thin rod of steel passing from it, and curved or bent at a right angle, to prevent any pressure or friction being made

against the lip; this rod is made to pass downwards, and long enough to extend about an inch and a half, or two inches, below the level of the chin. To this is attached a piece of wood for the chin to rest upon, shaped to the base of the jaw, and about half an inch or less in thickness, made to slide up and down by being fixed upon a thin plate of iron, which is perforated, to allow of it fitting

on the rod. Below this, and near the bottom of the rod, projects a small bar, through which a screw passes, reaching to the under part of the wood upon which the chin rests; so that by turning this screw it can be raised or depressed at pleasure. The accompanying drawing may perhaps assist the above description.

A, the grooved plate which rests on the teeth.

B, the rod, bent at right angles, connecting it, and upon which the chin-piece slides.

C, the chin-piece, on which the base of the jaw rests.

D, the screw which raises or depresses it, by passing through the projecting bar, E.

F, the key which turns the screw, made to take off.

G G, two holes for a bandage to pass through.

When applied it fits the jaw as follows:—The plate A, is placed on the incisor teeth, having been previously padded with lint or leather. The plate C, is placed beneath the chin, having also been well padded with lint. The screw D, is now turned until the plate C, on which the chin rests, is raised so as to bring it as near to the plate A, as the depth of the jaw will allow. The two portions of bone will thus be fixed between the pressure made by the plate A, and by the plate of wood C, and consequently prevent one portion of bone being depressed below the other; and the groove in the plate A, will prevent one being drawn behind the other. To make the instrument more secure, a bandage may be passed through the holes G G, and fastened at the back of

the neck and top of the head; this will prevent the instrument slipping forward. The screw is turned by the key F, which is made to take off, to prevent it pressing against the chest when the neck is bent, and also to prevent the patient loosening the instrument himself.

When the instrument is fixed, there is no fear of the apposition of the two portions of bone being disturbed by any motion that may be given to the lower jaw; and the great inconvenience of the ordinary mode of treatment is here done away with, viz. the necessity of keeping the lower jaw pressed constantly against the upper, as the only means of keeping the portions of bone at rest.

By the instrument here recommended, no such inconvenience exists, for the whole instrument being fixed to one

bone only, and not depending upon any other part for its position, will not be loosened at all by any motion that may be given to the jaw; for as the latter moves, the instrument will move with it, thus enabling the patient to eat with more facility, and to talk without fear of disturbing the position of the two portions of bone. But still unnecessary motion need not be given to the jaw by allowing the patient to eat food that requires mastication, or by taking too much.

The first case in which I tried the instrument, as previously mentioned, I did not succeed to my satisfaction, not being able to try its application for a sufficient length of time to effect a cure. There was great irritation about the soft parts within the mouth, causing the sublingual glands to be immensely swollen before I applied the instrument. But when I did apply it, it kept the two portions of bone perfectly fixed for four or five days, when I was obliged to discontinue it, owing to an attack of erysipelas coming on in the face, partly depending, no doubt, on the pressure of the instrument upon the soft parts, already in a state of irritation. The patient ultimately died of other injuries received at the same time, so that I had not an opportunity of continuing the application of the instrument.

The second case, and the one in which I lately tried it, was a little boy, admitted into the hospital during last month. The jaw was fractured exactly at the symphysis, between the two middle incisor teeth. In this case there was the same difficulty in keeping the two portions of bone in proper apposition, though not to so great an extent as in the former instance. Finding the ordinary means incapable of keeping the bone in proper position, I got permission to try the instrument, and to my great satisfaction found it perfectly successful, though this case presented disadvantageous circumstances, there being a small abscess beneath the chin, caused by a wound in the integuments inflicted at the time of the accident. This made me fear that the pressure requisite to produce the desired effect could not be borne; but by padding well with lint the part on which the chin rests, the difficulty was removed, this wound not being made worse by the pressure. The patient bore the instrument without any inconvenience;

was capable of taking food with facility, and of talking without producing any displacement of the fracture.

From this case, I have every reason to believe that the instrument will answer perfectly; more particularly where there is no injury done to the soft parts, to render pressure inapplicable. The first case certainly led me to think, from the accidental circumstance of the erysipelas arising, that the pressure would produce too much irritation to be borne; but this last case shews that the instrument can be borne without any irritation being caused; the patient having worn it for a fortnight, and with the disadvantage of having a wound already existing beneath the chin.

I think the instrument might also be adapted to those cases where the fracture is situated more laterally, by having the plate A extended to a sufficient length to press on the two portions of bone where the fracture exists, and curved to the shape of the jaw. The principle of its application will be the same here as at the symphysis.

The instrument, as I have had it since made by Mr. Thompson, of Great Windmill-Street, Haymarket, is very neat and light, and of sufficient strength to allow of the necessary pressure being made

CHEMICAL ANALYSIS OF SERUM AND URINE IN DISEASE.

To the Editor of the Medical Gazette.

SIR,

WE have taken the earliest opportunity of forwarding to you the following analyses of serum and urine obtained from patients labouring under anasarca with coagulable urine.—We are, sir,

Your obedient servants,

R. H. BRETT.

GOLDING BIRD.

Guy's Hospital, June 18, 1833.

100 grains of serum were carefully removed from the crassamentum about twenty-four hours after the blood had been drawn: it had an opaque milky aspect, specific gravity 1.014, and was subjected to the same mode of analysis as that described formerly for healthy serum, with a view of proving the absence or presence of urea, (the process in detail is inserted in the Gazette of the 13th July; we have, therefore, not

thought it necessary to repeat the steps in this instance) with the following results. For the sake of comparison, we have placed in juxta-position to this analysis the one formerly published of healthy serum.

	Healthy.	Diseased.
Water	88·63	92·11
Albumen	10·16	6·68
Peculiar animal matter, } with a portion of lactic acid	·48	·80
Chloride sodium	·62	·33
Carbonate of soda, re- } sulting from the de- composition of the lac- tate	·11	·08
	100·00	100·00

200 grains of urine, obtained from the same patient, and highly coagulable by heat, were evaporated over a salt water bath at a temperature of 219 degrees F. as nearly as possible to dryness: the residue was found to weigh 1·9375 grs. This was boiled with an excess of alcohol, specific gravity ·833, and the whole thrown upon a filter; the undissolved portion was then washed with repeated portions of boiling alcohol; the filtered liquor and washings were evaporated in a glass capsule to dryness at a temperature of 219 degrees F. and found to weigh ·8375 grains: it was treated with nitric acid, and crystalline plates of nitrate of urea obtained, mixed with an inconsiderable quantity of animal matter, not to be separated without much

difficulty and risk of loss from the urea. That portion of extract of urine insoluble in alcohol was then boiled in repeated portions of distilled water until the last drops which passed through the filter no longer affected nitrate of silver. The filtered fluid was then evaporated to dryness, and the residue found to weigh ·600 grains. This, after ignition, left a white ash, weighing ·300 grains, which, when dissolved in a very small portion of water, precipitated chloride of platinum and alcohol, chloride of barium, and, lastly, nitrate of silver. After the whole of the sulphuric acid had been removed by chloride of barium, the clear filtered and acidulated fluid gave a precipitate when super-saturated with ammonia, indicating the presence of an alkaline phosphate. The ·300 of ash, therefore, consisted of sulphate of potass, chloride of sodium, and phosphate of soda. That portion which remained insoluble in alcohol and water was ignited; it left a bulky charcoal, and evolved the odour of burnt feathers, and carbon was removed by continuing the heat, and the residue found to weigh ·0625 grains, which, deducted from the ·5000, the weight before ignition left for animal matter ·4375, which consisted of albumen, lithic acid, and mucus.

In order to compare with greater facility the proportions of the constituents of this diseased with healthy urine, the proportions in 1000 parts have been subjoined, together with Berzelius' analysis of healthy urine.

DISEASED.	
Water	990·3125
Urea and animal matter, so- } luble only in alcohol . . . }	4·1875
Ammoniacal salts and animal } matter, soluble only in water }	1·5000
Lithic Acid	a trace.
Albumen and mucus	2·1875
Alkaline sulphates, phosphates } and chlorides }	1·5000
Earthy phosphates	·3125
	1000·0000

HEALTHY.	
Water	931·05
Urea	30·10
Animal matter and ammoniacal } salts, soluble in water and al- } cohol }	22·24
Lithic Acid	1·00
Vesical mucus	·32
Alkaline sulphates, phosphates, } and chlorides }	14·26
Earthy phosphates	1·03
	1000·00

The deficiency of albumen and salts in the diseased serum is worthy of remark, as is also the presence of albumen and the great deficiency of the salts and animal matter in the diseased urine. Subsequent to the completion of the above analyses, we have had an op-

portunity of examining some serum and urine obtained from a patient labouring under the same disease, but which had so far yielded to remedies that the anasarca and coagulable state of the urine had almost entirely disappeared; not a trace of urea could be detected in the

serum, although there was a great deficiency of this substance in the urine: the salts were deficient in both fluids.

We may, we think, conclude from these circumstances, that urea, if it ever exist in the circulating fluid, cannot in any degree be a cause of the peculiar train of symptoms observed in patients labouring under coagulable urine with anasarca, inasmuch as all the usual characteristics of that disease have been found to be present without the slightest trace of urea being found in the blood, nor could that principle, if existing, have escaped notice when sought for by the processes above detailed; for if so minute a quantity as that shewn to be present in the urine of such patients can be eliminated from a fluid so complex and prone to decomposition, the same means would have been found adequate to the detection of much smaller quantities if existing in the serum of the blood, which is a much less complex and decomposable fluid.

ON THE
INJURIOUS EFFECTS OF MERCURY
IN SOME FORMS OF DISEASE.

To the Editor of the Medical Gazette.

SIR,

THERE is a state of disorder in children, occurring more frequently in those of scrofulous temperaments, which is evinced by languor, loss of appetite, a diminution, and sometimes a total cessation of the biliary secretion, with slight emaciation, more particularly of the extremities, in which my experience would declare that mercurial medicines are absolutely prejudicial, and yet how universally would such a train of symptoms be supposed to demand their free and continued use! Some years ago I was requested to see a child whose state, as nearly as possible, was as described above. Mercurials in moderate doses, with laxative and stomachic medicines, were prescribed, but in a few months the child died. Postmortem examination presented great alteration of structure in the abdominal cavity, more particularly in the liver and mesenteric glands: these local changes appeared to me a justification of my practice. Some

months afterwards I was requested to see another child of the same family, nearly under the same circumstances; but the anxiety of the parents, roused by the fatal termination of the first case, led them to apply to me when the child was in tolerable health, but the motions were colourless. I adopted a slight mercurial plan, &c. as before. The child from that hour became worse; lost appetite, flesh, and strength, and became as children do to whom mercurials are frequently given, unnaturally pale and unnaturally irritable. Under the care of a physician, who pointed out to me my error, the child, I may say, rapidly recovered. The slight mercurial plan adopted in this case soon produced a fearful change in his state of health, and at the time the *opinion* was taken, so reduced was the child, and in every appearance so resembled the former case, that I felt at the moment very little doubt the result would be death. It is no pleasing reflection, but it necessarily intrudes itself, that it was I who was producing disease by my very remedies, and those organic changes which post-mortem examination discovered in the first case, were, I fear, produced by the use of mercury. Should we not be cautious in the use of such a power? Some of its destructive effects on the system have been most ably pointed out to us by Mr. Swan, and it is impossible to peruse his "Inquiry into the Action of Mercury" without being struck with the deep importance of his observations. He leads us to believe that mercury produces a peculiar effect on the grand sympathetic nerves, seriously affecting all the organs of digestion, and also inducing a state of inflammation in the rectum. Yet with a knowledge of these facts, how inconsiderately is this valuable but dangerous remedy exhibited to children in the month, and why? because there may exist a disordered action in the bowels, or a discoloration of their contents. My own experience would declare that at that early age no circumstances would justify its use, or that it should be given with that extreme caution which would almost amount to a prohibition.

I was desired to see an infant whom I found in a convulsive paroxysm. It had vomited, and there had been two dejections of a greenish fluid from the bowels. The temperature of the body was low, and the child was pallid as a corpse. I

learnt that the day before the infant was in tolerable health, but its bowels had been a little disordered. A grain of calomel was given at night. The child vomited, was uneasy, and appeared occasionally faint. No relief from the bowels. Two grains of calomel were given in the morning. Within an hour after this, the child was in the state of collapse which I have described, presenting as frightful appearances as ever ushered in the most malignant disease. Ammonia restored the patient to animation. Ammonia, with rhubarb, quickly restored him to health. I adduce this as a striking instance of the baneful effects of mercury, and as an example of its injurious effects on the nervous system generally.

There is another consequence which I believe sometimes follows the frequent use of this medicine, which is *squinting*. I have witnessed this too frequently not to place some confidence in the opinion; and if we call to mind the close connexion which exists between the nerves supplying some of the muscles of the eye and the great sympathetic, Mr. Swan's opinions of mercury may receive some trifling confirmation, and my own no trifling support. It is true I have seen a slight inversion of the eye relieved by the administration of calomel and a black draught; but the relief, I believe, was obtained in consequence of the intestines being swept of their acrid contents, which were distressing nerves rendered morbidly irritable by the use of mercury: it was relieved, too, to return more strongly marked during each successive attack of indigestion.

To this latter form of indisposition, the use of mercury more particularly leads. As Mr. Swan justly observes, "it affects all parts concerned in digestion." I have attended children whose constitutions had been ruined by this medicine, with whom it is scarcely possible to believe the effects which a fit of indigestion would produce, and how frequently this derangement was occurring. Delirium, subsultus, hot skin, pulse 120, and even more frequent; yet all these formidable symptoms *instantaneously* subsiding on relief being obtained from the bowels, and sedatives (lettuce, hyoscyamus, &c.) administered.

I may be wrong in my conjectures, but I cannot help believing there are forms of disease also in which we can-

not administer this medicine without more or less of injury. In all the eruptive diseases I believe we ought to be extremely cautious in its use. Some time ago I was attending an adult in the measles. The symptoms ran high, and on the third day he was exceedingly oppressed by his burthen; coughing, breathing quickly, the face was swelled, and (as almost the whole body) was one mass of eruption; the pulse considerably more than 100. He had not in the early stage of the disease been distressed by powerful remedies, or reduced by *absolute* starvation. A physician of deserved eminence was consulted. He looked to the chest with most anxiety, and thought the inflammatory diathesis prevailed. Two grains of calomel, with two of James's powder, and an antimonial saline draught, were directed to be given every four hours, &c. I saw this patient two hours after the exhibition of the second dose of the medicine, and found him perfectly collected, but he was more restless, his pulse violently throbbing, and intermitting every sixth or seventh pulsation; his cough was more troublesome, and I was particularly struck with the change of colour in the skin; it had become almost purple. I ordered the following medicines, and strong beef-tea for nourishment.

R Acid. Sulph. dil. gtt. x. Mag. Sulph. 3ss.
Manna, 5j. Tr. Hyos. 3ss. Tr.
Card. c. 5j. Inf. Rosæ, 5x. M. f.
haust. 6tis horis. sumend.

In three days this patient was convalescent.

I do not think I err in supposing that in all forms of constitutional irritation, the result of injuries, its use is prejudicial. I believe I have seen great aggravation of the general disturbance occur on its exhibition, and I cannot from circumstances suppose that this increase of indisposition was merely the progress of disease. This observation is founded in some experience, and is rendered probable by the following opinions contained in Mr. Swan's Essay on Tetanus. He says, "after every accident in which the constitution sympathizes with the injured part, I believe the ganglia of the grand sympathetic nerves become irritated, and the functions of the parts supplied by them with nerves are disturbed in consequence. The action of the heart is increased in

proportion to this degree of irritation in them so long as it continues moderate.

I am, Sir,
Your obedient servant,
HENRY GEORGE.

CASE OF IDIOPATHIC GLOSSITIS.

To the Editor of the Medical Gazette.

SIR,

HAVING noticed in a recent number of your journal an interesting case of glossitis, which occurred in the practice of Messrs. Taynton and Williams, I have been induced to send you the following, which came under my own observation; and as I believe it to be one of no very frequent occurrence, it may prove worthy a place in the Gazette.

Henry Lane, aged 41, applied January 14th, with a swelling of the submaxillary glands, occupying the whole space between the angles of the jaw, and which occasioned slight difficulty in deglutition. The tongue moist, but covered with a creamy fur; pulse but little accelerated.

Ordered leeches and fomentations, with active purgation.

On the following day the glandular swelling became more painful, but in other respects the same. Leeches were again applied, and poultices directed to the part. During the night the tongue was affected with severe shooting pain, and rapid swelling supervened, so that, when called to him in the morning, I found it filling the entire cavity of the mouth, and partly protruding between the teeth; its mucous membrane appearing in spots of a vivid red, and the slightest touch giving most acute pain. Respiration extremely difficult, and quite unable to articulate or swallow; the pulse full and frequent. More active depletive measures were adopted; he was bled to $\frac{1}{2}$ xx., a large blister applied to the throat, clysters administered, and the mouth washed frequently with an astrigent gargle.

By this treatment in a few days the tongue and submaxillary glands regained their natural state; and nothing happened to retard the convalescence of the patient beyond the sloughing of a

small portion of the tongue, in consequence of pressure against the teeth.

I may remark here, that this is the only case I have met with of *idiopathic* glossitis; but I have known more than one instance where it has followed the sting of a wasp.

Yours, &c.

T. J. G.

TWO EXTRAORDINARY CASES OF FASTING.

DR. SCHMALZ, of Dresden, in a former No. of Hufeland's Journal, has related two very singular examples of abstinence from all food, protracted for an almost incredible length of time. We must remember, however, that he saw both individuals, and had an opportunity of personally ascertaining the particulars; and, moreover, the first case was the object of a Government inquiry.

Angelica Vlies was born in the neighbourhood of Delft, in South Holland, on 20th August, 1787. In her early years her constitution was very feeble and delicate, and she was much subject to cramps, induced by intestinal worms, which she voided both upwards and downwards in great quantities. She enjoyed tolerable health till 1811, about which time she was first seized with violent hysterical paroxysms; during these the bowels were obstinately confined. Subsequently she had repeated attacks of chronic enteritis, and her appetite, which had been throughout very sparing, now began to fail altogether. At one time better, and at another time worse, she continued in the above state till May 1818, when she discontinued the use of solid food entirely, and took nothing but drinks, chiefly whey. All medicines were rejected by vomiting as soon as swallowed. For upwards of four years she tasted nothing solid, with the exception occasionally of a little fish and salad, which she sucked, but never swallowed. In the spring of 1822 the attack of hysteria became so violent as to threaten death. An enema was given on the 10th of March; the bowels and also the bladder were then relieved; and this was the last time that any regular evacuation of stool or of urine took place. About this time she refused all nourishment whatsoever, fluid as well as solid;

and now the catamenia, which had hitherto been regular although scanty, ceased. She frequently moistened her mouth with a little cold water, to abate the burning heat she felt there. In July 1822 an erysipelas appeared on the abdomen; it was relieved by the constant use of bread and milk poultices. In the following year she had a severe attack of dyspnoea, and fixed pain in the left side of the chest. Her physician, Dr. Grootenbeer, ordered a blister. In 1824 she had repeated seizures of subacute arteritis. In 1825 these seizures were neither so frequent nor so severe; in October of this year she voided, after most excruciating suffering, a small quantity of urine and fieces. During 1826 she made urine twice, and at each time only a few drops. Thus, from the 10th March, 1822, to this period, she had had relief only once by stool, and three times by urine. The Dutch medical commission were very anxious at this time to induce her to remove to the Hague, in order that an opportunity might be had of strictly inquiring into her case; she would not, however, consent to this, but permitted four nurses to wait upon her alternately for the space of a month; the expense of their attendance was defrayed by Government. Soon afterwards a memoir was drawn up by Dr. Vorstman, and published at Delft in 1827. According to the authentic reports of the nurses, Angelica took no food, fluid or solid, from Nov. 11th to Dec. 9th. During this time she used to moisten her mouth with water, tea, or whey; but she invariably spat the fluid out again, and the quantity was thus frequently somewhat increased, and certainly never diminished. She had no evacuation by stool or urine, but had occasionally belchings of wind. During the day, she sewed and amused herself with reading. She rose, or rather was lifted from bed, at 9 A.M., and was carried back at 11 P.M.; but she slept very little, being much distressed with headache, swoonings, and cramp. Her age at this time was 41, but her appearance indicated more than 60 years, her face being shrivelled, and her eyes dull and lustreless; her tongue was clean and dry; the skin was parched; the pulse normal in frequency, but exceedingly weak and small; the sensibility of the cutaneous, and perhaps also of the deeper nerves, was so much impaired, that she was scarcely aware of her skin

being pinched or pricked. Every hour and a half she was seized with a shivering, followed by a convulsive lateral agitation of the head; these fits lasted generally for about two minutes.

Dr. Schmalz (the reporter of the case) visited her in September 1828, and had an opportunity of being perfectly satisfied with the truth of the preceding statements. She told him that she had not eaten nor drunk any thing since the report of the medical commission, nearly two years before; and if we go back, we shall find that this extraordinary abstinence had now lasted six years and a half, from March 1822. The patient told Dr. S. that she would very willingly take food, if she could in any way swallow it, but that this effort was impracticable to her.

Here the report ceases, and Angelica was still alive at the date of the report.

CASE II.—History of a Female who Lived upwards of 2½ Years without Food.

Professor Ricci, of Turin, has published a full detail of this case in the *Repertorio di Medicina et di Chimica di Torino*.

Anna Garbero, aged 40, had hitherto enjoyed moderately good health, although her appetite had been always remarkably sparing. Her food consisted generally of vegetables, only once a day; and the bowels were not usually relieved above twice a week. Gradually the appetite became less and less, and once she passed forty days without touching any solid or fluid aliment. But it was not till September 1825 that a total inappetence for food came on; it was after a very scanty meal, consisting of only a mouthful or two of cabbage, and a draught of wine and water, that she was seized at once with intense gastralgia, which continued for some time, till copious vomiting was induced. From this date she was unable to swallow any thing, and even her spittle was thrown back when she tried to allow it to pass down. Up to the 7th of the succeeding January she neither eat, drank, nor had any relief by urine or by stool; the only appreciable evacuation was that of the catamenia, which, though very sparing, returned regularly.

Dr. Schmalz visited her at this period; he found her so emaciated, that she seemed a mere skeleton, over which a dry skin had been forcibly stretched.

The skin was almost quite insensible to pricking, or to the strongest pressure; the limbs were cold and corpse-like; the pulse small and scarcely perceptible, but yet regular in frequency. The patient was quite willing to make an effort, at any time desired, to swallow food, but it was of no avail; and at length the mere sight of any victuals, however simple, brought on most painful vomitings. Things continued so till the end of June, at which time she became insensible and lethargic; this state of apathy continued till the 25th of the following November, when she quite suddenly and unexpectedly recovered her senses and speech. Her strength became weaker and weaker, and finally was exhausted in death on the 19th May, 1828.

The body was examined in the presence of Professors Rolando and Gallo, by whom a very interesting memoir was published at Turin; we give only the more interesting and illustrative details. The omentum majus was found drawn strongly downwards, and had become adherent to the brim of the pelvis, thus leaving the small intestines quite uncovered. This change had been caused by the falling down of the transverse colon, which was lying in the pelvic cavity; it was distended with hard feces. The small intestines were, on the contrary, contracted to mere cords. On carefully tracing the colon, it was found that the canal of the descending portion was so much obstructed by the swelling of its mucous lining, that the feces could only with difficulty be forced along. The obstruction was still greater at the commencement of the rectum, and completely prevented the transit of any solid matters. The contents of the ascending colon were more fluid, of a dark green meconium-like colour, and most intolerably fetid. Two lumbrici and several ascarides were found in the bowels.

The rationale or etiology of the preceding case appears sufficiently simple. We conceive that a chronic inflammation of the colon and rectum had been originally caused by exposure to the inclemencies of the weather, for the patient was a beggar. Thus, not only was the appetite directly impaired, but also the passage of the feculent matters obstructed, and the general health became more and more deranged in consequence. Complete anorexia was the consequence of the accumulation of the

feces; the colon was dragged down by the weight, and, at the same time, the stomach and œsophagus were necessarily displaced in a similar direction, and this displacement must have seriously injured their functions. Besides, traces of a slow inflammation of the mucous coats of the small bowels, and also of the stomach, were found upon dissection; and our readers need not be reminded of the effects which we daily observe to flow from such a morbid state. In short, we are to regard the preceding case as one of the melancholy results of neglected subacute enteritis, originally of the rectum and sigmoid flexure, and subsequently of the rest of the canal.—*Journ. der Pract. Heilkunde, and Med. Chir. Review.*

CASE OF EXTRAORDINARY CONGENITAL BULIMIA.

ANNE DENISE was born in 1786. From her earliest years her appetite was most voracious, requiring more than four times the allowance of other children. She menstruated at 7 years of age, and, at this period all the other attributes of puberty were developed. As she grew older her appetite became more insatiable; she was dismissed from school because she devoured the food of her schoolmates; she therefore gave lessons herself, and the only reward that she wanted for her instruction was meat and bread. At this time she eat ten pounds of bread daily. She could not, however, make sufficient by her present employment, and therefore she engaged as a servant in an hotel. Several times she had been arrested for stealing loaves from bakers' shops; and at length she was reduced to beggary, as no person would keep her in their employment. She used to wander about the streets in Paris, devouring all the refuse of food which she found at different doors. A great variety of remedies had been ineffectually employed to overcome this morbid hunger. She was admitted into the La Salpêtrière under MM. Esquirol and Amussat, for relief from epileptic attacks, to which she had been for several years subject. At that time she consumed from eight to ten pounds of bread daily; she drank very little. The bowels were confined; and she had two or three attacks of hæmatemesis every month. Occasionally her appetite be-

came prodigiously increased, and at these times she would devour twenty-four pounds of bread in the course of a night; she was literally mad with hunger at these periods, so that if she was thwarted, or food refused, she would begin to chew her clothes, or whatever she could get hold of. During these paroxysms of bulimia the epigastrium was found to be tender, and this tenderness was increased by pressure, and a profuse vomiting of blood generally ensued. This "grande faim" recurred only once a year, and always on the 9th of February. In the course of twenty-four hours she has been known to have devoured thirty-two pounds and upwards of food, eating and vomiting blood alternately, until she fell down quite exhausted. M. Rostan, in 1819, tried various means, chiefly antiphlogistic, with only temporary benefit. Ice was administered inwardly, and, for a time, considerably abated the fury of her hunger.

In 1823 she consulted M. Descurret (the reporter of the case), with the view of ascertaining whether there were any intestinal worms. He administered purgatives; several pieces of tænia were expelled. The appetite was considerably diminished, and she was satisfied with five pounds of bread, and two or three basons of soup daily; and the "grande faim" did not take place this year, and indeed did not return until 1828.

As her hunger decreased, she became intolerably addicted to the abuse of spirits, which in time brought on such a depravation of appetite, that she would devour the raw lights of the slaughtered animals, and afterwards literally brouse upon grass. In July 1828, having gone to her "favourite pasturage"!! she collected a quantity of grass and buttercups (*ranunculus acris*), which she eat for supper. During the night she was seized with torturing pains of the abdomen—jaundice ensued, and she died in a few days.

Dissection.—The stomach was small; the mucous membrane of it, and also of the intestines, was inflamed in patches, but otherwise healthy; the liver was very large; the other viscera sound. The condyles of the inferior maxilla were literally worn away! For further particulars, we refer our readers to the October No. of Broussais' *Annales de la Méd**.

LEGAL CLAIMS OF GENERAL PRACTITIONERS.

To the Editor of the Medical Gazette.

SIR,

THE proceedings of the northern Colleges upon the subject of the Act of the 55th Geo. III. having engaged the attention of the general practitioners of England and Wales, I beg leave to direct the attention of the licentiates of the Hall to a point of importance to those gentlemen whose vested rights are thus suddenly about to be abrogated. Previously, however, to the enunciation of the proposition in question, I beg to offer a few preliminary remarks upon the subject matter under consideration. A legislative act of the Imperial Parliament we necessarily consider one of the most solemn guarantees of the private property of individuals to which its protective clauses may extend. I take it to be a proposition which no person may contest with impunity, that when once the High Court of Parliament has *conditionally* guaranteed certain privileges to a body corporate, that upon the fulfilment of those conditions by the corporation in question, the Parliament is bound by law and equity to perform its part in the compact. Conditional compacts between the sovereign and the subject are coeval with the British constitution. All the real and personal estates of the subject may be considered in the light of tenures holden upon specific conditions. The proprietors of these estates are, in the eye of the law, tenants; the thing holden being styled a tenement, and the manner of their possession a tenure. Even the freeholds of inheritance are supposed to be holden mediately or immediately from the king, who is therefore considered as lord paramount of all the property in the realm. Thus amongst the conditional compacts we have the military tenures of the Norman Conqueror; but that which perhaps is more to the point in question—the socage tenure without escuage—a tenure holden from a superior lord upon the fulfilment of certain stipulated conditions. This species of compact is defined by Fleta, "ex donationibus servitia militaria vel magna serjantia non continentibus;" by Littleton, "as a tenement held of the lord by any certain service." The original laws of the socage tenures, springing apparently from the ancient feudal en-

feofments, were consolidated by the Statute of 12th Carol. II.; and from this consolidated statute may be deduced those almost infinite ramifications of chartered privileges which are styled monopolies in the present day.

Keeping, therefore, in view the original Norman statutes of military tenure, from which are deducible the socage tenures before us, and remembering that all conditional compacts are equally binding upon both parties, we will proceed to examine how far the Imperial Parliament is warranted in equity in the abrogation of the monopoly of the Company of Apothecaries. Previously to the enactment of Statute 55, Geo. III., the medical profession in England was in such a state of imperfection, as to demand the interposition of the Legislature. A bill was therefore brought into Parliament to rectify the abuses which were daily committed; the representatives of the people, as in duty bound, and the lords spiritual and temporal, concurred in the enactment of certain restrictions on the practice of the general practitioners of England and Wales, which restrictive enactments became the law of the land, having duly received the assent of the King. When, however, the restrictive enactments passed the Imperial Legislature, it was not to be supposed that such provisions would be carried through the national councils without some protective stipulations. The law was necessary for the health and well-being of his Majesty's subjects, enacted for the express purpose of furnishing them with a well-organized and accomplished band of medical practitioners—of persons competent to undertake the difficult task of combatting the diseases, and of superintending the public health of the community. The statute in question thus provided for one principal object—the public welfare. This provision could not be carried into effect without the aid of persons properly qualified to carry into operation the enactments of parliament; therefore, it was necessary that properly qualified agents should be induced to enter into the national compact. The inducements offered by the legislature were certain privileges and immunities as a compensation to the parties surrendering their time and devoting their talents to the attainment of that abstruse and peculiar knowledge, which was thenceforth to be made sub-

servient to the public welfare. Thus the knowledge acquired became a marketable commodity, and government engaged to become the vendees. In pursuance, therefore, of this scheme of compensation by the 55 Geo. III. an authority was delegated to a body of individuals to carry the compulsory clauses into execution, and this body assumed the style and title of “The Court of Examiners of the Company of Apothecaries.” They had the power of prohibiting individuals from practising as apothecaries who had not qualified themselves according to the statute of the 55th, Geo. III.; for, although they may not prescribe the specific course of studies to be pursued by the candidates, yet authority was conveyed to the corporation to prescribe such by-laws, for the better education of the candidates, as the Court might seem meet and proper. Chartered, therefore, by King James the First, and confirmed in their peculiar privileges by the 55th Geo. III. and 5th Geo. IV. &c. the corporation in question was fully authorized to carry into effect the provisions for which it was established. The monopoly of the Licentiates may be therefore styled an equitable monopoly, the ultimate object of which is the well-being of the public. Under this equitable monopoly, certain indemnifying privileges were *vested* in the Licentiates. They have performed their part in the legal covenant: they have fulfilled the conditions stipulated by act of parliament; and therefore, having purchased the privileges as their just indemnification, I contend that they stand seized with these privileges and immunities, and that the legal investiture so formed becomes *de facto* the private property of the tenurees. An infringement, therefore, of these privileges amounts to a trespass—an abrogation to a positive disseisin: therefore, if a devolution of the legal estate takes place, it can be considered in no other light than that of an imperial spoliation.

What remedy, then, have the Licentiates? can they prosecute the legislature as trespassers, or indict them for non-fulfilment of their own compacts? No; the parliament being omnipotent in national affairs, can be cited to no inferior tribunal. The sovereign may be persuaded in his own courts, but can never be compelled to rectify an injury unknowingly committed upon the sub-

jects; every infringement, therefore, of the public or private rights of individuals committed by the royal act, requires that the king should be informed in his own courts of such error, for it is presumed that the knowledge of a regal aggression is tantamount to its rectification. The legislative assembly being the highest court of justice in the realm, must necessarily have the principles of justice inherent in its constitution. It cannot, therefore, grant privileges and immunities in order to acquire the fulfilment of an object of national importance, and as soon as that object is attained, refuse the compensation awarded, for this would be an act of injustice, and therefore could not be sanctioned in the legislature. Therefore, if parliament in its wisdom should deem it expedient to recal its solemn guarantees, and to annihilate the privileges of the Licentiates, it is bound, by its own laws, to INDEMNIFY the sufferers.

If, then, the act now before the Select Committee of the House of Commons pass into a law, the legislative compact will be violated. The Northern diplomatsists will practise as apothecaries without examination, and the members of the Royal Colleges may demand an examination without undergoing the same ordeal that we have done. Now it is expressly enacted by the 55th Geo. III. that no person shall practise as an apothecary without serving an apprenticeship of five years to an apothecary; yet in the amended Bill, the apprenticeship clause is reduced to one year's attendance in the laboratory of a surgeon or apothecary. Thus is the former act virtually repealed. Let then the Licentiates keep their eyes steadily fixed on the progress of this Bill; let them pour in petitions for immediate indemnification. It matters not whether the admitted be Scotchmen or Irishmen, Medes, Persians, or the dwellers in Mesopotamia, the compact has been violated, and that not by the guarantees, but by the guarantors.

If the Court of Examiners had been so culpably negligent of their duty as to set on sale their diplomas to purchasers without reference to the capabilities of the candidates, then, indeed, might they have justly merited the indignation and vengeance of parliament, and a writ of *quo warranto* against the corporation might have been a suitable

punishment. But let us look at the state of the profession now, and compare it with the condition in which it appeared when the 55 Geo. III. was called into operation. Then the general practitioners were, comparatively speaking, ignorant of the fundamental principles of physiology; and the scientific practice of medicine was by no means well understood. Now the immense field required by the Court of Examiners for the student to exercise in, and the more comprehensive attainments which the Licentiates are expected to exhibit, have exalted the general practitioners in the eyes of the scientific world. Every curriculum from the Hall bears indubitable testimony of the indefatigable exertions of the Court of Examiners to elevate the professional candidates above the buffoonery of charlatanism and quackery. The Court has therefore done its duty—has gained the approbation of the Licentiates, and merited the applause of parliament. How, then, shall it be said that the privileges of their Licentiates are to be reduced to a mere bagatelle?—are they to be blown away by the northern whirlwind, “and, like the airy fabric of a vision, leave not a wreck behind?” Have the Licentiates been chary in imparting the benefits of their knowledge to the poor and needy in the moment of tribulation and anguish? Who came forwards in the hour of battle, when the pestilence tolled the knell of horror and mortality over these shuddering islands? Who entered the dens of desolation, and, without fee or compensation, the caverns of penury and prostitution—those damp deep cellars of wretchedness and misery, where the devouring plague was holding its abominable revels?—the members of the Royal College of Surgeons and Licentiates of the Hall—the general practitioners! And for these notable professional services—for the immense sacrifices which you then made—for all the personal pains and penalties you then endured—how has parliament rewarded you? Verily, your reward is yet to come, sons of Asclepiades! in the splendid spectacle of amercements and confiscations—of vested rights and chartered privileges annulled and annihilated—of solemn compacts and legal covenants trampled into the dust for ever! But this, to be sure, is the spirit of the age. If reform in our public institu-

tions means a contemptuous violation of all chartered rights and legal compacts, then woe to the reformed!

The reforming energies of the Parliament have been extended to those torrid zones where colonial property depends for existence upon its supreme jurisdiction; but there, when private property was trespassed upon, indemnification was awarded. In a neighbouring isle, where the property of the church was encroached upon, government awarded a species of indemnification in the shape of a purchase of tithes retrospectively; and shall it be said that the Licentiatees of the Hall, amounting to ten thousand respectable individuals, shall suffer a disfranchisement without indemnification? No: such a breach of faith in government would tend to shake the foundation of public trust, and insinuate a thousand alarms to those whose property is immediately dependent on the legislative will.

But what may be the amount of the claims of the Licentiatees upon government? The income of the Licentiatees of the Hall may be calculated at 8,000,000*l.* per annum. Now for the spoliation of these privileges, and the partial annihilation of this income, what indemnity will government award? Perhaps Lord Althorp may favour the Editor of the London Medical Gazette with his calculations. These subjects are merely thrown out as delicate hints to our professional brethren, respecting their pecuniary losses in expectancy. As for the profession, the injury which it will sustain no pecuniary indemnification can repair. The general practitioners will cease to retain the confidence of the public, and the curriculum of the Hall may be expected to graduate to the zero of professional qualifications.

I remain, sir,

Your obedient servant,

WM. JOHN THOMAS.

ON DISPENSARY ASSOCIATIONS.

To the Editor of the Medical Gazette.

SIR,

If your pages will allow of it, perhaps you will insert the following remarks on what are called Self-supporting Dispensaries; and I am the more anxious you

should do so, as there are one or two recommendations in a letter from Mr. Jones, of Derby, last week*, which I do not think the most conducive to the interests of these institutions.

The great difficulty in establishing them has almost invariably been the opposition of the medical men, afraid of their own interests. To shew them, however, how unfounded this fear is, I would take the liberty of referring them to a paper in the Appendix to the Report of the Poor Law Commission (it is printed in folio, for the use of the members), where there is rather a detailed account of these Dispensaries. It begins by endeavouring to remove the chief difficulty, and shewing that it is the interest of the medical men to support them. The argument is, that the poor who live by labour without capital, may be divided into those who are not only independent now, but can also prepare for sickness and age by joining a club; 2dly, those who are independent now, but cannot prepare for either; and, 3dly, the parochial poor. Now it is not very difficult, in some parishes, to calculate what these three classes pay for medicine and attendance, and we know from medical men, in some instances, what they do pay, as far as the profits from these classes can be separated from other profits. Again: it is not very difficult to shew what the same three classes would pay if they subscribed to a Dispensary, and if the rich, as is proposed, added something also; and the conclusion is, that the medical men would gain more money than they do at present, whilst there are instances to prove that they have so gained. Not that *every* medical man will gain more in every case: for, bad as the present system is, that individual who can secure to himself all the direct and greater indirect advantages from it will not be benefitted, though the profession collectively would be so.

Having endeavoured to shew this at length in the paper alluded to, I have then compared the original rules of Mr. Smith with the different modifications of them which have already been adopted in different circumstances, and shewn, by the results of experience, which of

* See p. 355, *ante*. We have to apologize to Dr. Calvert for so long deferring the publication of his letter; but it was done with the intention of letting his remarks appear simultaneously with our own, which we have not been able to find room for till now.

them are best adapted to secure the cordial co-operation of the medical, the honorary subscribers, and the poor. The details given on these points, and on the results of the trials already made, being more copious there than I have seen elsewhere, I would take the liberty of suggesting their perusal to those who wish for information on the subject, and particularly to those who would gladly assist if they had reasonable assurance that they would not sacrifice their interests to their philanthropy.

I should not recommend the Derby Dispensary as a model: indeed it has been too expensive to be adopted in most places: the practice of having charity patients, and of paying for the medicine of these out of the sum intended for the medical men, makes their remuneration inadequate; and, besides, numbers of poor are tempted to beg for charity tickets when they might pay for themselves. I believe it will be found, from the statements I have there given, that it is generally best not to allow of charity tickets at all, and to ensure to the medical men two-thirds of the independent subscriptions. If the expenses of medicine and management are not paid by the other one-third, the deficiency should be made good by honorary subscriptions from the rich. This plan alone makes it the common interest of the medical men and of the committee to increase the number of independent poor subscribers: the former see that two-thirds of the subscription, regularly and certainly paid, is better than their present state, and the committee see that the proportional expenses of medicines, &c. decrease with the increase of the members. I will not here go into the details as to what the subscriptions ought to be, and how they are to be modified by journees—how the parish poor are to be admitted, &c. &c.—nor will I say more of the benefits to be derived from these “Dispensary Associations,” (properly they are not Self-supporting,) than assure you that, after a careful consideration of almost every trial, successful and not yet made, I believe they combine the interests of the philanthropist, the medical man, and the poor, better than any plan which has yet been proposed for that object.

I remain, sir,

Your obedient servant,

J. M. CALVERT, M.D.

Ryde, June 16, 1833.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Infirmities of Genius illustrated by referring the Anomalies in the Literary Character to the Habits and Constitutional Peculiarities of Men of Genius. BY R. R. MADDEN, Esq. Author of “Travels in Turkey,” &c. In Two Volumes.

THE title of this work, we rather think, is calculated to mislead; it is somewhat too metaphysical. One would expect to find here nothing more than a series of essays, like D'Israeli's, on the literary character, whereas the main object of Mr. Madden's book is to describe the besetting bodily infirmities of literary men, and to explain how they generate and influence those peculiarities by which the children of genius are so commonly distinguished. The author is not unknown to our readers, who may recollect the interesting passages which we some time ago extracted from his “Travels;” he is a medical man, and as such, has, as he is well aware, peculiar advantages in analysing human character. In alluding to the biographer of Burns, he makes the following judicious observations:—

“It is rarely the lot of a wayward child of genius to have a Currie for his historian, and hence is it that frailties, which might have awakened sympathy, are now only mooted, to be remembered with abhorrence. It is greatly to be regretted that eminent medical men are not often to be met with qualified, like Dr. Currie, by literary attainments, as well as professional ability, for undertakings of this kind. No class of men have the means of obtaining so intimate a knowledge of human nature, so familiar an acquaintance with the unmasked mind. The secret thoughts of the invalid are as obvious as the symptoms of his disease: there is no deception in the sick chamber; the veil of the temple is removed, and humanity lies before the attendant, in all its truth, in all its helplessness, and for the honourable physician it lies—if we may be allowed the expression—in all its holiness. No such medical attendant, we venture to assert, ever went through a long life of practice, and had reason to think worse

of his fellow-men, for the knowledge of humanity he obtained at the bed-side of the sick. Far from it, the misintelligence, the misapprehension, that in society are the groundless source of the animosities which put even the feelings of the philanthropist to the test, are here unknown; the only wonder of the physician is, that amidst so much suffering as he is daily called to witness, human nature should be presented to his view in so good, and not unfrequently in so noble, an aspect."

From these remarks the reader may gather the principle on which the author of the volumes before us treats the mental peculiarities of Pope, Cowper, Byron, Burns, Johnson, and other illustrious literary men whom he incidentally notices. We know few themes more interesting. Men of letters are in general so deplorably negligent of their health, that living on, as many of them do, to a good old age, they cannot but be a standing paradox to many reflecting minds. "Surely," says Ficinus (as quoted by Mr. Madden), "scholars are the most foolish men in the world; other men look to their tools; a painter will wash his pencils—a smith will look to his hammer—a husbandman will mind his plough-irons—a huntsman will have a care of his hounds—a musician of his lute; scholars alone neglect that instrument which they daily use, by which they range over the world, and which by study is much consumed."

There is a curious table given by Mr. Madden, which shews how strikingly the longevity of literary men is influenced by the particular line of study in which they are engaged. The names and ages of twenty eminent persons are set down in each of twelve tables, according as they are natural or moral philosophers, medical authors, and so forth; their ages are then cast up, an average is struck, and the result is as follows:—

	Aggregate Years.	Average Years.
Natural Philosophers. . . .	1501	75
Moral Philosophers. . . .	1417	70
Sculptors and Painters. . .	1412	70
Authors on Law and Ju- risprudence	1394	69
Medical Authors	1368	68
Authors on Revealed Re- ligion	1350	67
Philologists	1323	66
Musical Composers. . . .	1284	64

Novelists and Miscellane- ous Authors	1257	62½
Dramatists.	1249	62
Authors on Natural Religion	1245	62
Poets	1141	57

Whence we may very clearly infer, that those pursuits in which the imagination is most largely exerted are the most unfavourable to longevity; and the average life of the poet is proved to be about one-fourth shorter than that of the natural philosopher. The fact being thus established, the author goes into the reasons of these diversities in the duration of life, and accounts for them very ably and ingeniously. We regret that our limits do not allow us to follow him regularly through his interesting pages; but there are a few miscellaneous remarks and passages which struck us in our perusal of the work, that may not be inappropriately extracted.

Among the various theories incidentally discussed, we find the author strongly supporting Sir H. Davy's notion of the identity of the electrical and the nervous energy. The biographer of Davy has ventured to call this "a theory which has scarcely a parallel in extravagance and absurdity;" but Mr. Madden, influenced by what he conceives to be weighty reasons, and which he sets forth at length, has no hesitation in saying that Dr. Paris's remark "has no parallel in presumption." We cannot enter into an examination of the subject here, but it will be found not the least interesting portion of the work before us.

When Dr. Johnson was about twenty years of age, full of hypochondria, he drew up a list of his infirmities for a Dr. Swinfen, and received a reply to his inquiries, importing that the description of symptoms which were detailed indicated a future *privation of reason*. One can readily imagine what an effect such a communication must have had upon the habitually gloomy student.

"No one, indeed, can wonder," says Mr. Madden, "that this terrible prognostic of insanity should cast its shadows before all his future hopes of worldly happiness: the only wonder is, that a physician could be found so ignorant of the moral duties of his calling, or so reckless of the feelings of a melancholy man, as to implant the very notion in his mind which it was his business to endeavour to eradicate, if al-

ready fixed there—namely, that madness was to be the termination of his disease. Was this doctor simple enough to imagine, that there is any thing in genius which renders the intellect better able to support prospective evil, or the undisguised prognosis of a fearful malady, than the humble faculties of an ordinary mind? Simple indeed he would be to think so, and little acquainted with human nature.

“But the error, we well know, is daily committed by the inexperienced, of supposing that literary men are possessed of strength of mind that may enable them to rise superior to the fears and apprehensions of the common invalid, and, consequently, that all reserve is to be laid aside, and the real condition of such patients freely and fearlessly exhibited to their view. This is a great mistake: the most powerful talents are generally united with the acutest sensibility, and in dealing with such cases the considerate physician has to encourage, and not to depress, the invalid: to temper candour with delicacy; and firmness, above all things, with gentleness of manner, and even kindness of heart. If it be essential in one disease more than another for the physician to command the confidence of his patient, to engage his respect, and to convince him of the personal interest that is taken in his health and well-being—that disease is morbid melancholy.”

The chapter on the last moments of men of genius is written with much force, and is full of interest. There is one topic in it which we cannot omit to notice—the explanation and illustration of the “lightness before death,” familiar to ancient observers, and popular still among the peasantry in some European countries. Sir H. Hallford not long since drew attention once more to the subject; and Mr. Madden so reasonably accounts for the phenomena, that we are tempted to give his words:—

“In truth, this lighting up of the mind amounts to nothing more than a pleasurable exciting condition of the mental faculties, following perhaps a state of previous torpor, and continuing a few hours, or oftentimes moments, before dissolution. This rousing up of the mind is probably produced by the stimulus of dark venous blood circulating through the arterial vessels of the brain, in consequence of the imperfect oxygenation of the blood in the lungs,

whose delicate air-cells become impeded by the deposition of mucus on the surface, which there is not sufficient energy in the absorbents to remove, and hence arises the rattling in the throat which commonly precedes death*.

“The effect of this new stimulus of dark-coloured blood in the arterial vessels, appears strongly to resemble the exhilarating effects of opium, inasmuch as physical pain is lulled, the sensations soothed, and the imagination exalted. Long-forgotten pleasures are recalled, old familiar faces are seen in the mind's eye, and well-remembered friends are communioned with, and the imaginative power of giving a real presence to the shadowy reproductions of memory is busily employed, and a sort of delirium, or rather of mental exaltation, is the consequence, in which a rapid succession of ideas, in most instances apparently of an agreeable nature, pass through the mind, and the sense of bodily pain to all appearance is wholly overpowered. These phenomena were, perhaps, never more strikingly exhibited than in the case of the late Mr. Salt. The last three or four days of his life, his mind seemed to have regained all its former activity. He spoke in various languages to his attendants, some of which, as the Amharic, he had not used for many years; he composed some verses that referred to his previous sufferings, and repeated them with great energy to the friend who accompanied him. The prophetic spirit which in some degree is supposed, by the authors we have alluded to, to be attained by the dying, was likewise aimed at, though not attained in this instance—for poor Salt frequently predicted that he would die on a Thursday, but the prediction was not accomplished.”

Of the sketches of character presented to us by Mr. Madden, that of Cowper is the one which pleases us most. It is the only approach to a rational biography of that amiable and highly-gifted poet that has yet been offered to the public. The author divests poor Cowper's malady of the obscurity and mystery in which it has been involved; and shews how terribly all the symptoms were aggravated by the counsel and

* In the Quarterly Review for April, the explanation of the phenomena here glanced at is sensibly and intelligibly given, and may be referred to with advantage for larger information on this subject.

conversation of injudicious people. The leading events in the history of Cowper's sufferings, so far as they concerned his health, and consequently his happiness, may be summed up in few words. From his earliest years, he was delicate in constitution and timid in disposition. Excessive application to professional studies in the Temple increased the delicacy of his health; the nervous system and the cerebral organs became disturbed or disordered in their functions; and his natural timidity merged into a morbid sensibility, which wholly disqualified him for the active duties of that profession in which he had been so improperly placed. The derangement of his health having obliged him to go to the sea-coast, he visited Southampton, and there his imagination converted the sudden appearance of a burst of sunshine into a visible manifestation of the presence of the Deity. The terror of a public appearance at the bar of the House of Lords, so injudiciously urged by his friends, quite broke down the little aptitude that was still in him to mingle in the business of public life. He became the victim of hypochondria. The vision at Southampton never was forgotten: it was a warning which he had neglected: repentance—remorse—despair—were the dreadful consequences. He always maintained that there was no hope for him here or hereafter. The wonder, indeed the miracle, is, that the poor monomaniac could have achieved such admirable performances, and so contrasted, as the Homer and the Hymns, during the short intervals of his melancholy disorder.

In sketching the career of Sir Walter Scott, and noticing the influence which the steady habits and physical peculiarities of that great man had upon the even tenor of his life, the author takes occasion to intersperse many sound medical precepts, touching the regulation of diet and exercise. It is worth observing that Mr. Madden, apparently through a well-conceived apprehension of the possibility of his book not becoming popular, should it be too medical, has ingeniously reserved most of his professional hints for his concluding pages. What he says, for example, about the importance of friction, is towards the conclusion of the second volume: we shall abstract it, as it is practical.

It is the *mode* of applying friction

by means of the flesh-brush, that, in the author's opinion, renders it so unpopular. A simple glove, made of common white druguet, without divisions for the fingers, except for the thumb, is the best thing that can be used for the extremities; and a common flesh-brush, covered with the same material, with a handle about fifteen inches in length, is by far the most convenient and effectual mode of applying friction to the body. "We are so thoroughly convinced," says Mr. Madden, "of the utility of the chafing glove, that however misplaced the mention of its advantages may seem to be in these pages, we still most strenuously venture to recommend its employment to those who have most need of exercise and least inclination, or perhaps opportunity, to take it; to those who are deprived by their pursuits of that insensible secretion of the skin which is essential to health, and the obstruction of which (as we have seen in the case of the unfortunate Cowper) is frequently the cause of the gravest maladies which afflict humanity."

To the medical man who has literary patients to deal with—and who that has patients at all, at the present day, has not among them some of the *irritable* tribe?—to literary men themselves, and to the public generally, who would at least be amused, if not instructed, we would strongly recommend the perusal of these volumes.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

SELF-SUPPORTING DISPENSARIES.

SINCE last we called the attention of our readers to the subject of Self-supporting Dispensaries—now several months ago—experience has been every day adding its sanction to the system; the mists of prejudice and error which were raised by some, who fancied themselves interested in shewing opposition, have been

gradually dispelled, or are become so transparent that there is no longer any difficulty in obtaining an unobstructed view of its simple mode of working. It is true that the sphere of those Dispensaries is as yet comparatively limited, and that their progress in becoming multiplied throughout the country is not very rapid. This, however, we are confident is owing to nothing heavy or unmanageable in their machinery, but rather, perhaps, to the habitual dislike of innovation, for which the steadier classes of people in this country are distinguished:—though certainly the charge of innovation is scarcely any longer applicable to the Self-supporting Dispensaries: that of Southam, the first fruits of Mr. Smith's benevolent exertions, has been instituted now, we think, about ten years; many others have been gradually established since; the Derby has had a successful trial of about three years, and the Coventry Dispensary is flourishing for above two. Of these and several others we have received accounts from gentlemen on whose candour we place every reliance: some of these accounts we have published, and some have been given to the public through other sources. There is, we repeat, no novelty about the system; its details and its results are no secrets; and it is high time, we think, for all those who are advocates for the amelioration of the physical and moral state of the people, as well as for the comfort and respectability especially of country practitioners, to come forward and put their good designs into execution.

There has been, as all the world knows, a great Society established among us within the last few years—we mean that for the Diffusion of Useful Knowledge. Would that this body began at the right end, or that at least it bestowed some little share of its attention to promote what would really

tend to the diffusion of useful knowledge! Here would be a topic and a theme for the inculcation of sound principles. Let the principle of the Self-supporting Dispensaries be advocated, or even explained. The Society boasts of its circulation of above 200,000 copies a week; thus drawing from the pockets of the people, in pence, nearly 50,000*l.* a year: could not such a Society *afford* to discuss the value of Self-supporting Dispensaries?—could it not, among its other lessons of economy, point out the great importance of first securing health, and after that leisure for reading with advantage? Nobody can admire the Society more than we do, for its excellent exertions in the cause of the mental improvement of the people; but we must once more respectfully suggest, that as long as it neglects the opportunity of recommending the *self-provident* system of dispensaries, and thus, in the first place, providing for the blessing of health, so long do they proceed—not wisely.

It is for no invidious purpose that we introduce this reference to the management of one of the most active societies that this country has ever seen: but we own we are not a little jealous of the immense power, for good or for evil, which it possesses, and which it might readily employ for so admirable a purpose; and perhaps, also (while we see so large a sum gathered weekly from the poorer classes), we are somewhat indignant that there should any where be a complaint that funds for self-supporting dispensaries are deficient. We should like, for example, to know how many of the penny magazines sell at Derby, while it is maintained by some (among them by our correspondent Mr. Jones) that a charity class of patients is indispensable in that town, so large a proportion being unable to pay a penny a week for medical assistance. We confess we are strongly inclined to

be stern economists in this matter, and to deny the claims even of the poorest to gratuitous medical aid, when a penny a week, withheld, if need be, from the Diffusion society, could relieve them from much of their distress.

But poverty is not the great obstacle to the establishment of these dispensaries: from all we have been able to learn, there must be mismanagement where a *charity* class of patients is kept up, participating in the advantages of the provident members. It is unfair to the latter class, and, in fact, deprives the institution of its best claim to be considered as *self-supporting*. If there be a town in England which should seem likely to require indispensibly the admission of charity patients to the benefits of any of its medical institutions, that town is Coventry; yet from Dr. Arrowsmith's valuable communication*, we find that such a class there is entirely obviated. There, out of a population of nearly 30,000, it is calculated that about three thousand are so poor, exclusive of paupers, as to be unable to procure medical aid in the ordinary way; yet things are so well managed that there is no charity class in Coventry—the whole expenses are paid by the free members and honorary subscribers. And, by the way, what can more remarkably prove the great economy of a well-regulated Self-supporting Dispensary, than the financial returns made at Coventry? On the old plan—the patients doing nothing for themselves—how to raise the requisite funds was always the difficult and painful question. Two hundred pounds a year were known not to be adequate to provide for the medical wants of 300 patients, leaving little or nothing for the medical men. Under the self-provident system, 140*l.* from honorary subscribers, contributes to the relief of 3000 poor people, and leaves nearly

300*l.* for the medical attendants, medicines and all being paid for! Not to speak profanely, here we seem to have a miracle of loaves and fishes. But the explanation of it is this: the funds proceeding from honorary subscribers secure, in the first instance, a certain degree of patronage for the institution; the committee of management consists of this class; it is understood that they pay for every thing in the shape of house-rent, &c.—leaving the remuneration of the medical men and the expense of drugs to come from the contributions of the free members. Thus the whole principle of the *self-supporting* dispensary is preserved, however some may fastidiously object to the name. We agree cordially in Dr. Arrowsmith's remark on the propriety of retaining the original name, happily given to these institutions by their originator; and we are not sure that any principle is served by the title of Dispensary Associations, suggested by Dr. Calvert. "Self-supporting" they were intended to be, and such it ought to be the great aim to render them, whether they be for the present aided by honorary subscriptions or not. Ultimately let it be hoped that the "free members" will be able to disburse all the expenses themselves, and thus realize the expectations of all who patronized the plan from the commencement.

It is a fact no less true than it is remarkable, that wherever the Self-supporting Dispensary system has been introduced, the number of applicants for parish relief has diminished; and not only have persons been prevented by it from falling into the class of paupers, but by its good management and example, persons have been raised from the latter class, and been enabled to enrol themselves among the free members. Thus is the system not only preventive, but restorative. There is nothing mysterious in these results to the reflecting

* See p. 427, *ante*.

mind. Under the old system, illness at once throws on the parish the poor man, who has not the means of calling in medical advice—or who is unwilling to contract debts too large for him to pay. Nor does the evil rest here: there may be at first a sinking of the spirit on approaching the precincts of the poor-house, but once the barrier is passed, we know from too many examples that, bitter though they be, the unfortunate is tempted to enjoy the fruits of indolence. The difficulty is in breaking the charm, and ascending to upper air again: yet this is known in many instances to have been done.

“Without the co-operation of their own virtuous endeavours,” as Dr. Chalmers says, “there seems no possible way of doing good to the labouring classes, or of helping them upwards from a lower to a more secure and elevated place in the commonwealth.” In no way, perhaps, are those endeavours more fostered and encouraged than by the system which is here advocated. Habits of economy and independence are generated in the humble labourer: he is in as easy a state of mind regarding his health as any of his more opulent neighbours. He has a voice in procuring himself good treatment: he does not approach his medical adviser like a beggar—his humiliating condition pressing on his heart with all the weight of mortality: he feels that he has a claim on his medical adviser, and that he is no longer to be looked upon as dirt, or treated as one of a herd of squalid and diseased wretches, without distinction of age or sex. And above all, and which ought surely to recommend the system to the profession, he is taught to recognize the just claims of his medical attendant to remuneration: this perhaps will be admitted to be not the *least* valuable among the habits inculcated by the self-provident system.

We never could understand why in some places the attempt to institute these Dispensaries should prove unpopular—and meet above all with professional opposition: the advantages to the medical man are so obvious and so numerous, that one would imagine that they would be adopted at once, and every where by acclamation. Let us only consider the old method, or what we would fain call the method *formerly* in use: the patients were seen in a crowd: quite too numerous to be examined with any thing like accuracy or attention, or even sometimes common decency: habits of indifference and hard-heartedness were almost invariably and necessarily induced: there being no division of labour—one or two individuals being charged with the management of a multitude—no advantage could be reaped for the advancement of science, or even the ordinary improvement of the practitioner; on the contrary, the habit of prescribing carelessly and cursorily was eminently calculated to confirm him in his immature opinions and his undigested methods of practice. Now, all this is obviated in the new description of dispensary. There is in it as little as possible of the old system of monopolizing practice; there is in it a fair opening offered for the regular commencement of business by junior practitioners; there is in it, moreover, such a division of labour, and such an ease and satisfaction in the performance of it, as must be most conducive to individual and general utility. And when to this we add, that the self-provident system relieves the practitioner from the odious necessity of practising mean arts—in underselling his brethren for the sake of the paltry patronage of sick clubs and farming paupers of the parish; when he is no longer obliged to sue his patients in a Court of Requests, obtaining perhaps an order for the payment of his demands by in-

stalments of 6d. a week; when he considers that by the success of the self-provident system, he is saved from a multitude of unreasonable calls for his gratuitous assistance; and when, what must be most gratifying to every feeling mind, he is relieved from the necessity of claiming and urging payment from poor wretches on whom payment must entail privation: all these things being considered, we must repeat that we cannot understand the grounds of opposition which can with any shew of reason be offered to Mr. Smith's dispensaries by, above all people, medical practitioners. Is it that they prefer the chance of remuneration from those who, they suspect, would under the new system avail themselves of free membership? A short answer from a pamphlet of Dr. Arrowsmith's will dispose of this question. "Experience justifies a complete reliance on the feelings of the community on this point; for in the institution of the older title, and of identical principle—in benefit societies—no provision exists to exclude any individual from sharing in their advantages. Every person who applies for admission may be admitted, and is admitted; and although instances of the occasional introduction of ineligible persons cannot be doubted, yet so rarely do they occur, that it would be difficult, perhaps impossible, to discover any instance where a medical man declined to take charge of a society on the ground that the members were not suitable objects for such an institution. Referring to experience, therefore, we should be justified in anticipating that, on the large scale, improper persons would not avail themselves of the advantages of the self-supporting dispensary, even if the supervision proposed by the committee were not adopted.*"

In conclusion, for the present—for we are by no means done with the subject—we must confess our surprise that, extensively as it has been adopted in the country, the self-supporting dispensary plan has never yet had a fair trial in town. One would think that here were all the requisite materials for testing it on a proper scale. There is, or has been, a society in London for promoting the objects of self-supporting dispensaries, at the head of which we recollect the name of Lord Althorp. We should be glad to hear something of the proceedings of this society; but we must for the present have done.

THE LATE JURY OF MATRONS AT NORWICH.

It will be recollected that, in March last, a woman was left for execution, her plea of pregnancy having been set aside by a jury of matrons, who, after an hour's examination, pronounced her not pregnant with a quick child; but that she was afterwards reprieved, in consequence of a professional examination by three medical gentlemen, who reported her to be beyond the fifth month of pregnancy with a living child. We are glad to find ourselves borne out, by the following document, in the view which we took of the case*; and we trust that no further proof will be wanting to shew the danger of abiding by the old law-form, which ordains that, in similar circumstances, a jury of women, from among those present in Court, shall be sworn. The Norwich jury of matrons will, we hope, be the last of the kind.

To the Editor of the Medical Gazette.

Norwich, July 17, 1833.

SIR,—We beg to announce to you that Mary Wright, the prisoner in our county gaol, who in March last received a reprieve of her sentence of death, in consequence of our certifying that she was above five months gone in pregnancy, was safely delivered of a

* Defence of the Principle of a Self-supporting Dispensary, &c. by R. Arrowsmith, M.D. Coventry, 1831.

* See page 22, *ante*.

healthy female child on Thursday last, the 11th instant.

(Signed) P. N. SCOTT,
Surgeon to the County Gaol.

JOHN GREEN CROSSE,
Surgeon to the Norfolk and Norwich
Hospital.

J. GODWIN JOHNSON,
Assistant-Surgeon to the Norfolk
and Norwich Hospital.

MEDICAL FORCE OF PARIS.

It appears from a late return made by the Prefecture of the Seine, that there are at present 1652 medical practitioners practising in Paris. Of these, 879 are Doctors of Medicine of the new school; 36 Doctors of Surgery of the same; 109 *Officiers de Santé*; 256 Midwives; 9 Physicians of the old school; 18 Physicians of other faculties than those of Paris; 14 *Officiers de Santé*, with certificates instead of diplomas; 12 Midwives of the same class; 19 Foreign Physicians, authorized to practise; and 300 Practitioners, who have no qualification. The last item is certainly curious—nearly a fifth part of the *corps médicale* of Paris unqualified!—and this when we consider that the profession in France is so immediately under the care and cognizance of government!

MEMOIR OF RUDOLPHI.

BY PROFESSOR LINK, OF BERLIN.

(Condensed from the Original, in the *Berliner Medicinische Zeitung*.)

KARL ASMUND RUDOLPHI was born at Stockholm, on the 14th of July, 1771. His father was a clergyman, and co-rector of the German school in the Swedish capital, where he died in 1778, leaving his wife, with two children, in very straitened circumstances. The widow removed to Stralsund, her native place, in the following year. The eldest son, who was put to trade, went out to the East Indies about the year 1790, and has not been heard of since. Karl Asmund received the rudiments of his education at Stockholm; but on the removal of the family to Stralsund, he was received into the Gymnasium of that town, and remained there for eleven years. During this period there happened an incident that had nearly al-

tered the whole complexion of his future life. In 1786 an offer was made to his mother, by H. Gräff, the bookseller, of Leipsic, to take Karl as an apprentice; the offer was accepted, and the boy was sent to his intended master; but he was doomed to suffer a disappointment: another boy had already been received, so that young Rudolphi had only to return again to his studies; nothing loath, as it would seem, for he formed a determination thenceforth to apply himself undeviatingly to literary and scientific pursuits.

Rudolphi made good use of his school opportunities. His productions shew that he wrote Latin correctly, without, however, aiming at elegance. He also spoke that language well, and read Greek, though not fluently. He had a talent also for modern languages: besides the Swedish, he spoke French and Italian, and could read, though he could not speak, English. During the last two years of his residence at Stralsund, he acquired the rudiments of entomology, under the able guidance of the senator Schneider, and used to devote his leisure hours to botany, with the assistance of two accomplished friends.

In 1790 he entered the University of Greifswald, and closely attended, in the first instance, the business of the philosophical faculty. To botany also he gave much attention, and Quistorp, the professor, was so well pleased with him that he appointed him his assistant, and took him into his house, where he enjoyed opportunities of the most important and valuable kind. Rudolphi had an excellent talent for descriptive botany, as his papers in Schrader's Journal, even at this early period, prove. His attachment to botanical pursuits was, indeed, remarkable to the last; and during the career of his life he contributed much to diffuse a love for the science. The present Professor of Botany at Dorpat, Von Ledebur, was his pupil; and Willdenow has honoured Rudolphi by giving his name (*Rudolphia*) to a species of the Leguminosæ.

Having taken his first degree in the philosophical faculty, he defended a thesis, *Observationes circa Vermes Intestinales*, with a view to the doctorate in medicine. In this inaugural performance he first published the observations which he had instituted during the preceding two years and a half, on the subject of intestinal worms. In the

latter part of the year 1794 he was enabled to visit Jena, where he attended Hufeland's lectures and formed an intimacy with Batsch, who procured his election as a member of the Natural History Society of that place. He afterwards took a pedestrian tour through Dresden, Karlsbad, Erlangen, Fulda, Göttingen, and the Harz, back to Greifswald, where he arrived in the autumn; and after defending the second part of his thesis, already mentioned, obtained his degree. The year following, he was appointed a *Privatim Docens* in the Medical Faculty; on which occasion he read an essay—*De Ventriculis Cerebri*.

For a very short time about this period he turned his attention to practice, but believing that he could not well connect this with his other studies, he abandoned it, and devoted himself altogether to an academic life. He gave lectures in medicine and in natural history, and occupied himself specially with comparative anatomy and microscopical inquiries. It is, perhaps, not much to be regretted that Rudolphi thus early gave up the practical part of his profession, as he was in consequence enabled to devote himself with so much the more ardour to a more limited and favourite object. Every *savant* ought to be more or less an exclusive and an enthusiast in his own particular province, if he would cultivate it with success, and especially if he would be an able teacher.

In the year 1800, I find that he published a small volume of *Poems*, but at the same time formed a resolution to write no more poetry. These poems I have never happened to see. All his works, with the exception of these, he presented to me a few years ago, when he requested a similar favour in return. I should think that Rudolphi was deficient neither in the vivacity of thought, nor the feeling, nor the powers of description, requisite to express himself poetically; but he certainly wanted that acquaintance with a manifold variety of life—and, of course, all the fancy that hangs thereby—which would enable him to be distinguished as a poet, and of this he seems to have been pretty well aware.

When Baron Von Essen, the Governor General of Swedish Pomorania erected a chair of veterinary medicine at Greifswald, and Rudolphi was nominated the first professor, the latter set

out for Berlin, where he speedily made himself acquainted with the arrangements of the veterinary school in this place, and was fortunate enough to obtain the friendliest assistance from Professor Sick. About this time he lost his beloved wife, to whom he was united in the year 1797. She left him two daughters.

In the spring of 1802 were published his *Anatomico-Physiological Essays*, in which he partly gave an enlarged edition of certain papers which had already appeared in Reil's Archives—on the sensible atmosphere of the Nerves—on the formation of the Teeth—and on the intestinal Villi: and partly added others on the Peyerian Glands, Hydatids, &c.

After this he journeyed through Holland to Paris; thence through Lyons, Montpellier, and Grenoble, to Switzerland; and through Vienna and Prague home again. His remarks on this tour were published in 1804-5. During his progress he was chosen a member of the medical societies of Paris and Montpellier, and received an invitation to become a member of the Imperial Academy of Sciences of St. Petersburg for the section of anatomy and botany. The latter honour, however, he declined, as well as the appointment which was offered him of the Professorship of anatomy at Upsal. But he did not break off his connexion with the Russian academy: he published his celebrated essay against Gall, *Dubia contra Josephi Gall, de Organis in Cerebro distinctis usq. Cranii ope detegendis, hypothesin*, in the 14th vol. of the *Nova Acta Acad. Petropol.* and was presently honoured with the title of corresponding member.

It was a striking characteristic of Rudolphi's researches that they were of so general a nature and so comprehensive; and the tendency of all his observations, it may be noticed, went principally to the determination of matters of fact. His inquiries generally had reference to some prevailing, or even only curiously entertained, opinion. His shewing that the moisture in the cranial cavity was only accidental, refuted the opinion that the soul moved in that fluidity. It was held that the hair was tubular, as that of plants really is: Rudolphi showed that the contrary was the fact. Blumenbach had asserted that the Peyerian and Meyerian glands were only consequences of a morbid condition:

Rudolphi established them as distinct organs. Much had been said about the villi of the intestines since Lieberkühn's time: Rudolphi showed that the ampullæ were only accidental enlargements of the lacteals, and that the tubiform villi are only found in the mammalia. His paper against Gall, above mentioned, is unquestionably the best scientific refutation of a fanciful hypothesis, or rather charlatanery, which should have been properly treated only with derision.

When the Royal Society of Göttingen offered a prize for the best paper on the anatomy of plants, Rudolphi wrote for it, and I had the honour of dividing it with him. This, perhaps, may be the best place for mentioning how an acquaintance took place between us. Upon my returning from my Portuguese tour home to Rostock, Rudolphi sent me some dry plants, that I might give him my opinion of them. Thus a correspondence arose between us, chiefly on botanical subjects. I have never been in regular correspondence with above three men in my life, of whom Rudolphi was one, for I do not willingly write letters. We wished to be acquainted with one another, and Rudolphi came to see me in the autumn of 1805, and staid at my house for about twelve days. We used to begin to talk early in the morning, and kept it up regularly till late at night; yet when he was going away, we still had much to say to each other. We agreed before parting to work for the Göttingen prize. He thought the remuneration was too inconsiderable for so much trouble, and he accordingly begged the Royal Society to allow him to give the prize-piece for publication—a request which was readily granted. We were in this prize-writing almost always of opposite opinions. In general we were at very considerable variance on scientific questions, and had little scruple in animadverting on each other by name. Rudolphi speaks against me in several places of his physiology; and we were, particularly in our oral intercourse, in a constant scientific warfare—never, however, personal, of course.

In 1808-10 appeared at Amsterdam his greatest work, on which he had long laboured with ardour—*Entozoorum Historia Naturalis*, 3 vols. 8vo. This classical production will keep his name in remembrance as long as the know-

ledge of intestinal worms is a subject of discussion. It is not alone the indefatigable industry which it displays, but its most exact spirit of observation, which raises it to the first rank in natural history. In the introduction he defends the equivocal generation very ingeniously. A great number of species, first discovered by the author, adorned the work. An abstract of the whole, with additions and improvements, appeared in 1819, with the title of *Synopsis Entozoorum*.

In 1801 he was appointed assessor of the College of Health, and Professor of Veterinary Medicine. In 1808 he obtained the ordinary professorship of medicine, which was vacant by the removal of Kletten to Wittenberg. That same year and the following he had the good fortune to pay a part of the debt which he owed Swedish Pomerania for many good deeds vouchsafed to him. A murrain was brought into the land by a herd of Polish cattle, which Marshal Soult, with the best intentions, had presented to the country. Rudolphi recognized it immediately, and informed the Royal Government Commission that the murrain was present, and demanded the speediest methods to be taken. Two physicians in Stralsund doubted, and wished the Commission to stay a moment. But Rudolphi did not remit his zeal, and challenged those physicians to an immediate and common investigation: and so fortunate was he in his endeavours, that the herds were lost only out of two estates. The course of the infection was now but too well known; yet perhaps it ought rather to be considered lucky, that in consequence of the dispute, full conviction was obtained, and the proper methods were taken with effect, Rudolphi being appointed commissioner, with full power to have them executed. The following year, in consequence of the lung disease which clearly showed itself to be contagious, he was again commissioned to proceed through a part of Pomerania, when with little aid he was equally successful.

He now received successively invitations to Königsberg, Dorpat, and Berlin; the last of which he accepted, and went thither as Professor of Anatomy and member of the Royal Academy of Sciences, in the beginning of July 1810. Somewhat anterior to this period he had married a second time, Wilhelmine,

the eldest daughter of the magistrate Meyer, in Greifswald, who presented him with three daughters, all of whom died in infancy, and one son, now living, and a doctor of medicine. Rudolphi survived this union also: his second wife died in Dec. 1821. Rudolphi's mild, amiable character, his constant attachment to what he loved, made him an excellent, perhaps even too good, a husband. Upon the death of her daughters, his wife fell into a state of mental derangement: she considered her misfortune as a punishment from God. Rudolphi suffered very much in consequence, and the state of his mind on this account very probably laid the foundation of his liver complaint.

At Berlin he found an opportunity of displaying his talents as a teacher. He lectured in winter on anatomy generally, and on pathological anatomy; he also explained the anatomical preparations: in summer he lectured on physiological and comparative anatomy. Besides, he lectured two hours every week publicly on several subjects—medical encyclopædia—intestinal worms—manifestations of the mind, and so forth. His animated, perspicuously arranged, and orderly delivery, had a great effect. His business as a teacher went first; his literary works followed; and it may here be mentioned, that what others did for him in his youth, he now repaid richly to all diligent young men who made application to him. He gave them directions for their studies, he replied willingly to all their inquiries, he accommodated them with the use of his library—yes, and he benevolently aided, and richly too, their poverty. As he worked himself at his own pursuits with enthusiastic zeal, so he easily inspired with the same enthusiasm all the young men who loved to be about him.

Soon after his arrival in Berlin, he became director of the Anatomical Museum; it contained at that time no more than Walther's collection. The Zoological Museum has been for the most part created by Rudolphi, inasmuch as he with great activity had the animals procured at his own private expense, and had them prepared by the young people under his direction. He also became soon after his arrival member of the scientific Deputation for Medical Affairs. His correct and acute judgment, and the practical bearing of all his works, leave a chasm which cannot

easily be supplied. In 1812 he published a contribution to anthropology and general natural history. What he here first broached, he afterwards expanded more at large in his physiology. In the supplement of his life he gives himself as the author of the following inaugural dissertations:—*De Hyana*; *De Rana Pipa*; *Observationes Osteologicae*; *De Varietatibus Musculorum*, Diss. 2. They are rich in original remarks. It was at that time not yet forbidden the professors to write dissertations for the aspirants to the doctorate, as it formerly was almost a universal practice. The question on this point has two sides. Certainly a dissertation ought to be a specimen of the attainments of the aspirant, not of the professor. Yet the former, who may be under the necessity of having his dissertations written by another, can have it so done by whom he pleases; and thus we very often obtain valueless papers, instead of the valuable ones which the professors could supply.

Rudolphi's essays in the papers of the Academy of Sciences are very manifold, and contain many memorable inquiries; *e. g.* on the *Balana Longimana*—on the Poison Spur of the *Ornithorhynchus*—on the Transformation of the Ourang-outang into a Pongo—on Human Hermaphrodites generally, and on a genuine specimen of the kind, &c. &c. Almost throughout we see the tendency of the author to demolish rash and overhasty theories. His principal work at this period of his life was his *Physiology*, in 3 vols. 1821-8. It is a great loss to science that this work is not complete, nor ever to be completed; for among the fragments which remain, there is no more to be found than some extracts thrown together on the secretion of urine. It is an ample collection of matters of fact; and not merely a collection, but a critical discussion of them, executed with great acuteness. That was wanted. We have so many theories, and their abundance is become so wearisome, that we are very glad to take a general view, when the authors are not altogether infallible. This work, however, fragment though it is, will be named when other writings of the kind are forgotten: *Opinionum commenta delet dies*.

His ample income he spent, for the most part, on his library. The University was well attended by students of

medicine, and at that period there were not so many poor scholars among them as there have been since. He took also a good deal of money for fees. Besides, he lived moderately: he possessed, in 1832, the same furniture which he bought in 1810. When any one dined with him, all was simple in the highest degree; he drank wine, probably too much for his health, but it was ordinary red wine; it was only for a friend who would rather take none at all than common wine, that the friendly Rudolphi would have a flask of Burgundy fetched, when he knew of the visit beforehand. His anatomical and physical library one may pronounce to have been almost perfect: he was himself of that opinion. His Zoological Library was very rich. As he had no more books to buy, he collected medals of celebrated Savans; and his collection ought to be very considerable. I am not acquainted with it; I have an idiosyncrasy against such collections, and I told him so.

Rudolphi hated physics, because he believed that truth was disfigured through its hypotheses. "When one presumes that he can settle things *à priori*," as he says somewhere in his Physiology, "one easily gets convinced in this way." This peculiarity of his views should not be forgotten when a judgment is formed of his opinions. Some years after his arrival in Berlin, animal magnetism caused a sensation, and soon after began to gain ground. A commission was appointed to inquire into the thing; Rudolphi was a member, and thought to expose the fraud. Such commissions are of some worth when miracles are performed by a groom, but dangerous when ladies of quality busy themselves therewith. Rudolphi's upright correct mind could endure no deception: he unfortunately lost his temper in the transactions of this time; he could not laugh at them, for he used wit and humour only for things rather unimportant in themselves, not for matters which he considered serious. With this feeling he connected together his frequent thoughts on the question of a sensible nervous atmosphere, which he would not on any account admit. Perhaps he was wrong; in this, however, he was certainly right—that characters cannot be read through the pit of the stomach.

In the year 1817 he made an eight months' tour in Italy. The mild, open,

richly-informed man, who also had his information always present—who, besides, did not fail in talent for speaking—made a great impression wherever he shewed himself. Della Chiaia, at Naples, Ranzani, in Bologna, and Configliachi, at Como, spoke for a long time after with the liveliest interest of him. It was Rudolphi's last tour; the otherwise active man could no more be induced to any journey. In the same year he was appointed of the Medical Privy Council; in 1821 he received the Royal Prussian Order of the Red Eagle (3rd class), and in 1828 the Royal Swedish Order of the Polar Star. Since that he was named a member of several learned societies, &c.

He now withdrew himself gradually from all society, but continued at home to be the same cheerful and diligent person. About eight years ago he suffered very severely from spasm of the chest, and at the time made his will. He drank a great deal of Seltzer water, and now an incontinence of urine set in, which, no doubt, was his principal reason for withdrawing himself from society. As he ceased to drink, his complaint also ceased; but suddenly a dropsy of the belly ensued, in August 1832. He was still very active in mind when I saw him, about the end of October, on my return from a tour. He had no confidence in internal remedies: he used warm vapour-baths, which were serviceable at first, but he soon became weaker. He ultimately fell into a soporose condition, in which he died on the 29th November. He gave me some commissions a few days before his death with great composure; and almost his last words to me were, "I am certainly dying;" which he said with great calmness. On examining his body, much water was found in the abdomen; almost none in the chest. The liver was diseased.

ST. BARTHOLOMEW'S HOSPITAL.

Osteo-sarcomatous Tumor of the Lower Jaw — Operation—Cure.

ALICE GODWYN, aged 26, a healthy looking country-woman, married, was admitted into Faith ward, under the care of Mr. Lawrence, in the early part of June, with a tumor, situated on the right side of the

face, partly upon the outer surface of the base of the inferior maxillary bone, and passing deeply beneath the lower margin. The tumor was irregularly oval in shape, its long diameter extending from the angle to the symphysis of the jaw: it appeared firm, and solid in texture, and was moveable upon the parts beneath, except at the angle of the jaw, to which it seemed to be attached: handling occasioned no uneasiness, but she has at times experienced severe lancinating pains in it: the integuments covering it are natural in appearance, except that there were several cicatrices, the result of the local applications which had been made to the tumor. On the inner surface of the lower jaw, near the last molar tooth, was a fistulous aperture, through which a probe passed into the swelling, and from which a fetid, dark-coloured fluid, occasionally escaped. The patient states that the tumor commenced five years ago, in the form of a small knot, which continued slowly and progressively to enlarge, unattended with any particular degree of pain. Two years after its commencement it burst, and discharged a quantity of matter into the month, through the opening in the maxillary bone, which we have just mentioned: it subsequently increased in size, and its growth has latterly been much more rapid, and attended with greater pain. Her health does not appear at all impaired, and during the last nine months she has suckled a child.

22d.—To-day the woman was brought into the operating theatre, and Mr. Lawrence proceeded to remove the tumor in the following manner:—An incision was made through the long axis of the tumor, extending from the symphysis to the angle of the jaw: a second incision, commencing from the centre of the first, was carried vertically downwards, to the lower border of the swelling. The integuments were now reflected, forming two flaps, so as to expose the tumor, which was found to be contained in a cyst: the operator then dissected the tumor from the external surface of the jaw, to as great an extent as could be effected by the scalpel, in doing which the facial artery was divided and tied. To permit the attachments of the tumor, below and beneath, to be more freely examined, it was found necessary to slice through and remove the greater portion of it: a large artery was wounded at this part of the operation, but was immediately secured. The remaining part of the tumor was attached to the angle of the jaw, and passed deeply beneath the bone towards the cavity of the mouth: the connexions with the maxilla were separated with the bone forceps, and the tumor, together with the cyst, were dissected from

the parts to which they were attached beneath the jaw, except a small portion of the latter, which could not be removed without cutting through the mucous membrane covering the floor of the mouth. The edges of the wound were then brought together, and united by sutures, and a cloth wetted with saturnine wash ordered to be thrown over the parts.

Mr. Lawrence afterwards examined the tumor, which in the greater part of its extent was of a fibrous texture, the remaining part consisting of bone and cartilaginous substance: in the centre was a cavity, which had been opened by the section of the tumor made during the operation: it contained a dark-coloured, glairy fluid, of a fetid odour.

Mr. Lawrence, in addressing the pupils, related to them the circumstances of the case, and the character of the swelling previous to the operation, which we have already described: he had never, he said, met with a tumor of a kind exactly similar to this, which he considered to be of the nature of osteosarcoma: it was certainly not of a malignant nature, and as the small portion of the cyst would be thrown off by suppurative processes, he had no doubt but that complete and permanent recovery would ensue.

23d.—Has passed a quiet night; wound looking well.

25th.—The sutures removed; the edges of the incision along the base of the jaw have united by the first intention; there is a healthy discharge from the lower part of the wound.

July 16th.—The wound has continued to heal without any unfavourable occurrence, and the woman is on the point of being discharged from the hospital.

ANNIVERSARY MEETING OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

WE are much rejoiced to learn that the meeting at Bristol on Friday last, to use the language of a correspondent, "far exceeded in interest the most sanguine expectations of its warmest friends and supporters. At the Infirmary, in the morning, nearly 200 members assembled, and the proceedings were of the most gratifying description." From the Bristol Mirror of Saturday we extract the following particulars:—

"Yesterday our Infirmary was complimented with the distinguished honour

of being the place selected for holding the first anniversary meeting of the above Society, in consequence of the very numerous list of members and the respectable support given to the association by the most eminent professional gentlemen of this city.

[Here there is given a sketch of the origin and objects of the society, with which our readers are already acquainted.]

“Previously to the commencement of the business of the day, the exterior of the Infirmary, the internal arrangement of the wards, the new buildings, appropriated solely for the out-patients, the museum, the library, the lecture-room, and the whole economy of the institution, became an object of universal attraction and approbation.

“At eleven o'clock the members of the council met in the Infirmary committee-room, preliminary to the general meeting at one, about which hour this institution presented a scene of unusual professional ardour and interest, by the arrival of nearly two hundred members from different parts of the kingdom. Dr. Carrick was unanimously called to the chair.

“The meeting was opened by Dr. Carrick with an introductory and luminous speech; Dr. Hastings, honorary secretary to the society, then read the report; after which several resolutions were carried, and a council was formed to conduct and manage the affairs of the association. The business of the society being so far completed, Dr. Barlow, of Bath, delivered an eloquent and learned address, containing a retrospective view of the state of medical and surgical science, which occupied nearly an hour. This oration was received with universal satisfaction and delight, and unanimously ordered to be inserted in the next volume of the transactions of the society.

“About half-past four o'clock, the morning meeting being concluded, the company separated, and met again at half-past six, with several additional members, and sat down to dinner in the spacious banqueting-room at Ivatt's Hotel, when Dr. Carrick again took the chair, and Mr. Richard Smith and Mr. Hetling acted as vice-presidents. Nothing could exceed the harmony and conviviality of this entertainment.

“There never has been, on any occasion, such an assemblage of provincial talent and character convened together, either in this or any other country — altogether forming a new era in the history of the profession. As citizens of Bristol, we feel an honest pride in our ancient city having been selected for the first anniversary meeting of this valuable and scientific association; and we most sin-

cerely wish it permanence, success, and prosperity.”

We regret that we have not room for the names of the many distinguished persons from all parts of the country who attended the meeting; but we cannot close this account of the proceedings of the Association without expressing our cordial concurrence in the sentiments of our Bristol contemporary; we can fully estimate the growing importance of the society, and we need scarcely add that we wish it every success. Next year, we understand, the annual meeting is to take place at Birmingham.

—
DISEASES OF THE STOMACH AND
BOWELS.
—

DIARRHŒA.

I now proceed to the consideration of that disease into which chronic dysentery degenerates, but which happens every day (indeed I may say every hour) without dysentery—viz. diarrhœa.

Definition.—By diarrhœa is meant frequent, liquid, and rather copious, feculent stools (in dysentery the stools are not feculent), not dependent upon debility of the sphincter ani. When a person is weak in the sphincter ani he may have stools every ten minutes, but he would not on that account labour under diarrhœa.

In this disease there is only pain at the time of the evacuation. It is pinching enough, and even pretty sharp then, but it ceases as soon as the person has found a convenient place; whereas, in dysentery, the griping is horrid, and is not lessened from the discharge of mucus and blood which characterizes the disease.

Cullen, in his definition, says there is no preliminary fever, and that the disease is not contagious; but there may be preliminary fever in diarrhœa, inasmuch as it is frequently inflammatory. I should be content with the definition I have given.

Nature of the Dejections.—Now the discharge in this disease is of all colours—white, green, black, yellow, clay-coloured, and of various colours at various times; and it is also of all fortors—sour, fetid,

and every variety of unpleasant smell: it may likewise be bloody, watery, mucous, or purulent. Occasionally the motions can hardly be called liquid—they are only very soft. Sometimes they are uniform in their tenacity or softness, and sometimes it is dispersed in different portions. It appears that the discharge is chiefly an increased secretion of the intestines, and sometimes of the liver. Sometimes the nature of the discharge is dependent upon some other organ. The discharge may be purulent from an abscess in the liver, or perhaps in the ovaria.

Degrees and Duration.—There are all degrees of the disease, and all durations of it.

Morbid Appearances.—After death you will sometimes find nothing—it has been merely an excessive secretion; and, on the other hand, you will frequently find all degrees of redness and congestion. Frequently the mucous membrane is found softened, and then it may be red or white: sometimes it is inflammatory softening, and then it is red; and sometimes it is without any mark of inflammation, and is quite white. Occasionally the mucous membrane is found very much thickened, and it is also ulcerated. Sometimes the ulceration is a mere superficial abrasion, and sometimes it is very deep—it appears to have begun in the mucous follicles. The mucous follicles may contain (as in chronic dysentery) curdy stuff, and sometimes pus. The follicles are frequently in a state of hypertrophy, and sometimes without being ulcerated, they contain pus. In fact you have all the various states of the intestines which I mentioned as being seen after fever, and seen, indeed, in chronic dysentery. These may occur in the large intestines or the small intestines, or both; sometimes very extensively and sometimes partially.

Causes.—The causes of the disease are, in the first place, too much food. If a person eats a great deal, it must find its way, and it does. There must be more expor-

tation in proportion to the importation; so that diarrhœa is very frequently an effort of nature, and the person would be badly off if he had not diarrhœa. An alderman, I should think, would suffer severely if he had not many attacks of diarrhœa in the course of a season. Improper articles of food will give rise to diarrhœa; every body knows that if he take something which disagrees with him, he will suffer from it; nature makes a proper effort to get rid of it. Frequently new articles will occasion diarrhœa. If a person eat something to which he is not accustomed, although it is excellent in its kind, it will frequently give rise to the disease. Children suffer exceedingly if they are weaned too early, or too suddenly. There is a particular kind of diarrhœa in infants, called *weaning thrush*. If children be weaned before nature is ready for it, or if the change be made too rapidly, diarrhœa takes place; they cannot bear the sudden change from milk to common food; whereas, if the child be strong, and is weaned gradually, it bears the alteration of diet very well. This is precisely analogous to what is observed with regard to fish. There are salt water and fresh water mollusca; and if you put the salt water into fresh water, and *vice versâ*, they will die; but if you mix the water gradually, so as to lessen the saline quality of the water by degrees, it will live in it as well as if it had been always accustomed to it; and so with regard to the fresh water mollusca living in salt water. A new article of food is, both in children and adults, a common cause of diarrhœa, but especially in the former.

Cold is another common cause of this complaint, especially after heat. The mind too has a very great effect. Fear is generally considered to operate very strongly on the intestines. Malaria is enumerated among the causes of this disease. The suppression of other discharges will sometimes produce it. If a person have been accustomed to a running of the leg, and it is suddenly stopped, he may think himself well off if he have diarrhœa, because, if he had not, he might have apoplexy. Metastases are causes of it; if another disease cease, it is common to see diarrhœa begin. If inflammation suddenly cease, diarrhœa may occur. Dysentery is mentioned as one cause of it.

This is an affection which is very commonly produced by other diseases, or it becomes a part or consequence of other diseases. In fever, for instance, diarrhœa is very common; it becomes a part of fever. It is very common after measles; measles affect the intestines almost, I was going to say, as much as the skin, but it affects them in a very remarkable degree. So again in phthisis; the same state of the

body that gives rise to that affection at last causes a great irritation of the alimentary canal.

Causes of paroxysms.—Besides the exciting causes of the disease itself, there are exciting causes of paroxysms, if I may so call them. For instance, when a person is labouring under diarrhœa, if he move about much, he will very likely be obliged to go to stool; and again, on taking food, many persons immediately have a desire for a motion. Sometimes it is warm, and sometimes it is cold food, which has this effect. Frequently persons can take nothing warm without having a desire to go to stool; and the application of cold to the surface will bring on the desire in a moment. The best thing is to sit quietly by the fire without moving.

Treatment.—As to the treatment of this disease, if it be slight it is best to do nothing at all; it is generally a mere effort of nature to relieve herself from something improper, which has been taken inwardly, or from the depressive action of an agent applied to some other part of the body. When cold has been applied to the surface, nature relieves herself in this way; and if the individual do not make it worse, he is sure to get better.

But if it be necessary to adopt any measures, mild diluents in the first instance are the best things. Every old woman knows that barley-water, chicken-broth, and so on, help to soothe the intestines. Some persons to this add mild purgatives, and some are in the habit of giving the patient a dose of physic whenever he has diarrhœa, and in general there is no harm in it. If any thing acrid have been taken, it may aid nature, and the disease may cease so much the sooner; but if there be merely an excessive action going on, from a depressed circulation of the surface, or the passions of the mind, one cannot see what good can be done by a purgative. As the disease, however, in most instances, if left to itself, would cease without any thing at all, a purgative frequently has the credit of curing it when it deserves no credit at all.

If, however, the disease run on, it may be necessary to stop it, and for this purpose various opiates and astringents are given. It would be well in these cases to avoid giving tinctures, because there is frequently an inflammatory state, and an astringent is just as good without the alcohol as with it. I need not enumerate chalk mixture, catechu, kino, and all the various modes in which opium is given. In very severe cases the same treatment should be adopted as in chronic dysentery—the exhibition of sulphate of copper and other astringents. For what I know to the contrary, you might give it with safety

at the beginning: I have done so, but it is too powerful an astringent to be frequently required. Sulphuric, nitric, and muriatic acids, united with opium, have been given in these cases as in dysentery. Dr. Moses Griffiths, who invented a mixture of iron called *mistura ferri composita*, recommended in diarrhœa a mixture, consisting of two drachms and a half of tincture of rhubarb and six drachms of linseed-oil, a portion of which was to be given two or three times a-day. I have known this administered with good effect. The rhubarb, besides being a moderate purgative, is an astringent, and the oil is an emulcent. The one soothes, the other astringes; and it is thus that it has a good effect in chronic diarrhœa. It is also given in chronic dysentery. You will find it in some of the hospital pharmacopœias. It is a very beastly thing, as vile as can be well conceived; and I myself never found it necessary to give it, but it is sometimes a good medicine in the disease.

It is always necessary carefully to ascertain whether the disease is not inflammatory; after measles, it generally is to a certain degree, and you should always press the abdomen and see whether there is tenderness, because you may in vain give diluents, opiates, and astringents, and even make the patient worse by them than if you did not give them at all, if there be a degree of inflammation which you do not take means to remedy. I have seen many cases of diarrhœa which have resisted all the means that could be adopted, but which ceased presently on applying leeches to the part, or on the application of a blister. In fact, this disease is frequently nothing but an inflammation of the mucous membrane, and it will cease if you apply blisters. It is frequently necessary while you are doing this to give opium and astringents, and you may do so with perfect safety if you attend to the inflammation: indeed, if you do attend to it, there is frequently no occasion to give them at all; and if you do not attend to it, you make the patient worse by their exhibition.

The first thing, therefore, in cases of this disease, is to inquire into the cause. If the patient have been eating improper articles of food, you must change his diet; if there be any inflammation, you must treat it accordingly; if there be no inflammation, or not much, then you must exhibit opiates and astringents, and you will cure the disease. The mildest of all astringents is chalk mixture and a little laudanum; but if that will not answer the purpose, you must go on to catechu, kino, and sulphate of copper, taking care that the patient should be well purged in this

disease, just as I mentioned in chronic dysentery.

This is the common form of diarrhœa; occasionally, however, we meet with some singularities in this disease.

You will recollect that I mentioned Dr. Baillie having described a particular kind of jaundice, remarkable for its being green, and remarkable for its ending unfavourably. He also has described a kind of diarrhœa remarkable for the fœces being white, and likewise terminating for the most part fatally.

You will find this described by him in the Transactions of the College of Physicians. He says that in this particular kind of diarrhœa, the stools are white, like a mixture of lime and water, that is to say, like thin mortar, or mortar spoiled, frothy, and of a sour smell, very copious, and very numerous, unattended with pain, and the disease is so chronic that it may last for years. It most commonly occurs, he says, in men, not in women, and more particularly in men who have been in warm climates, and suffered from liver disease. He says that the affection may be occasionally suspended, and the fœces will sometimes become brown; but the disease returns, the motions become white again, and also become fluid, and the affection is very rarely removed; but the patient wastes away under it, and dies.

Now this is a disease which I have occasionally seen, and though Dr. Baillie could not cure it, I have been successful by treating it the same as ordinary diarrhœa. I have been successful in two cases which I have had of it, by persevering steadily with the exhibition of sulphate of copper and opium. Without giving mercury, the motions of these persons became bilious, they ceased to be white, and at last they became firm, as well as of a proper colour. One man was a patient in the hospital: he got stout, regained his looks, and would not stay any longer. His disease might return a year or two afterwards; but I kept him there a considerable time, and he remained perfectly well. He had been in hot climates, and in all respects corresponded with Dr. Baillie's observations. The other case occurred in a gentleman who had long been in India, and after persevering for nearly two years in the medicine, the disease, I understand, has entirely ceased. He is an old man, and his constitution has altogether given way to the warmth of the climate. He has had attacks first of one thing, and then of another, but his diarrhœa is perfectly cured. Dr. Baillie mentions that he has tried the ordinary remedies of kino, catechu, and chalk mixture, but that they have all been unsatisfactory, and all failed;

but by persevering with sulphate of copper and opium (sulphate of copper alone might have done,) and giving tonics at the same time, two cases have done well.

You will occasionally see in diarrhœa very considerable shreds of lymph discharged. Patients tell you that they have discharged great pieces of skin—that they are sure the coats of their bowels are coming off, and medical men have thought the same thing. Dr. Baillie once believed that he saw a portion of mucous membrane come away; but he afterwards detected his error, and said that it was nothing more than an effusion of lymph, corresponding to a serous membrane, and exactly like those tubercular substances which sometimes come away from the air-passages. Occasionally a large quantity of fibrin is secreted in the inner surface of the mucous membrane in chronic dysentery, and it will come away in the form of large shreds or tubes.

I have always seen this form of the disease marked by great pain, and I have found it exceedingly obstinate. I have not seen more than three or four cases; but by the most persevering treatment, I have not done any good; I have merely afforded temporary relief.

DISCHARGE OF FATTY MATTERS FROM THE ALIMENTARY CANAL AND URINARY ORGANS.

There is another still more curious sort of discharge from the alimentary canal, and that is a discharge of fat both in a liquid and solid state. Sometimes this is discharged with diarrhœa, and sometimes without it. Occasionally, the lumps come away with great pain; in other cases, it is oil that comes away, just of the colour of melted butter.

My attention has been attracted to it from having had some cases of this description under my own care. I was led to read upon the subject, and my curiosity was excited. I find that Sauvages, whom I mentioned as having been the first framer of a system of nosology, has mentioned a *diarrhœa adiposa*; and he says that he has known seneka, after hard riding, pour forth adipose matter. He says that it was apparently absorbed by the bloodvessels, where being mixed with the blood, it rendered it viscid: it then partly flowed into the intestinal canal, and there covered the faeces, as it were, with butter. That is his description of it. I find, however, several very satisfactory cases of this disease. There is one of a woman who discharged every day, for fourteen months, a large quantity of yellow fat, which lay on the faeces like melted butter. Sufficient was collected to fill a number of vessels, and when thrown into the fire it burned with a

bright flame; and after the faeces had cooled, it concreted of the consistence of absolute fat. But what was singular, there was neither tenesmus, emaciation, nor colliquative fever; and sixteen years afterwards she was in excellent health. This case is related by Tulpus; but he says, "What is this to an old woman who, in her 70th year, voided precisely similar fat from the intestines and bladder?" These are singular cases, but I believe them. Tulpus adds, that towards the close of the disease in the last case, the patient became feverish, and in consequence emaciated, and that death found her little else than a parched and juiceless corpse. I find another case where a patient for some years had suffered pain in the stomach; nothing relieved her, and she became worse, when one day she discharged about three pounds of fat, and from that moment speedily recovered. I find another case where a patient discharged from his bowels for two years a large quantity of fatty substance; he grew thin and weak, then died. In the Edinburgh Medical Essays you will find a case described which occurred to a weaver, 40 years of age, who, in attempting to take up a very heavy vessel, felt his back bone crack, which was attended with violent pain. He fell to the ground, being unable to stand. The pain long continued very severe; he fancied that the bone was dislocated inwards; and to reduce it, made one of his neighbours pull his belly backwards; while another, getting on his shoulders, pressed them downwards and forwards, by which he thought his loins were much straighter than formerly, and he had less pain. Some days after this, a country bone-setter undertook to put all the bones right, making one man pull at his shoulders and the other at his legs, in a contrary direction. By this extension he was put to most exquisite torture, and all his complaints were increased. Three months after he could just creep enough to crawl out of doors, and then observed among his excrements a whitish substance, about the bulk of a large walnut: it was like tallow, or hardened marrow, composed of small globules. It melted on the application of heat. During several days after, he observed several pieces of the same sort of substance, of the size of kidney beans or peas come away among his faeces. He thought all those lesser pieces, if they had been put together, would have been equal to the large piece he passed first.

About a year and a half ago I had a patient, in St. Thomas's Hospital, with diabetes, who had wasted away. For some reason or other I happened to see his motions, and there was lying upon the faeces a large quantity of fatty matter—soft fat;

which, he said, was quite fluid when discharged. I looked at the fæces regularly every day, and there was always one or two table-spoonsful of this fatty matter. I took a part of it to Dr. Prout and some to Mr. Faraday, and it was seen by some of the first chemists in London, who found it to be similar to fat. The question asked was, whether the patient had taken castor-oil? but he had taken nothing of the kind—nothing oleaginous. The fat ran away in this liquid form with his motions, or after them, and when he had diarrhœa it came at the top. It was voided like oil, but presently concremented. His wife told me that this was the first symptom of his complaint. He had formerly discharged an immense quantity of it, so that full one-half his motions were fat. What was curious, the disease ceased while he was under my care. He died of diabetes and phthisis. I opened him, but there was nothing particular to be found. The diabetes had arisen from an organic disease of the kidneys, but there was nothing else to be found there. The intestines looked greasy enough—they were like paper steeped in oil; but that was all. No oil was found in the alimentary canal. Dr. Prout tells me, that in cases of this kind which have come to his knowledge, there was considerable disease of the kidney. Mr. Pearson, of Clapham, shewed me a quantity of fat which came from an old woman, and said he could furnish me with any quantity. He understood from her that it was in the urine; but he mentioned the case of a lady whom he knew very well (he did not attend upon her, but he had been in company with her), who discharged fat both in the urine and fæces. He had been particular to have the urine by itself, and also to ascertain whether it came from the bowels or not; and he clearly ascertained that it came from both. In this case of his, and in my case too, I think the motions were very white: they seemed to be of a viscid nature. It is a curious disease. Mr. Howship mentions a case, in his book on Morbid Anatomy, of a lady who discharged a great quantity of this, and she was cured by giving her a pint of sweet oil. That was an odd remedy. He says she took a pint of sweet oil, and was well from that day, though she had long been previously ill. However, as facts are stubborn things, I gave the man under my care four ounces of olive oil, and the voiding of fat greatly diminished from that time, and soon ceased: whether the circumstance was accidental or not I cannot tell. You will find a case mentioned in Hufeland's Journal for 1826, of a quantity of thick oily matter being vomited: there was extreme emaciation, and a rapid dis-

charge of thick oily matter from the stomach.

I suppose you are aware that the spermaceti whale is liable to this disease: that what is called *ambergris* is fat which is collected in the intestines of spermaceti whales? As much as 182 lbs. have been found in, or discharged from, the intestines of that animal; and it is said that it has never been found higher than six or seven feet above the anus. This fat is very often discharged, and found upon the shore; but occasionally it accumulates, and the animal dies either from the accumulation or from disease forming in the intestine; I do not know which.

GASTRO-INTESTINAL CONCRETIONS.

This leads me to speak of concretions of the alimentary canal, which are sometimes discharged and sometimes collected within; and as they are sometimes found in the stomach as well as the intestines, we may speak of them altogether, under the head of gastro-intestinal concretions.

Now, in the first place, these concretions may occur without any fault in the gastro-intestinal canal; they may arise from the gall passages. Of course if a gall-stone escapes from the ducts, but is not voided, it will be found in the stomach or intestines. Dr. Marcet says that he once found a stone in the alimentary canal which came from the urinary passages: ulceration had taken place, and a communication had been formed between the urinary passages and the fæcal. The rectum, in this case, was imperforate.

Occasionally very hard concretions are found, which are nothing more than hardened fæces, and then they are called *scybalæ*; but occasionally these things consist of articles which have been swallowed. I saw a man who had swallowed nineteen clasped knives. He was not believed for some time, but he assured me that he had swallowed them, and, to convince me, he took one of the same size out of his pocket as those he had already swallowed, and put it down his throat. I was frightened, and begged he would bring it up, but it was too far gone. Some persons believed him, and others did not; but at last we could feel them sticking in the abdomen, and ultimately they could be felt, I understand, in the rectum. He discharged fæces containing a large quantity of iron, blackened; and at last he died in the most horrid torments, the knives cutting his intestines to pieces. The fastenings of the knives, as solution went on, of course became less and less secure, the handles separated, and the blades were let loose. After death, a great

quantity of knives were found in his abdomen, some having run through two or three folds of the intestines. It was a frightful sight. Considerable portions of the knives were discharged during life; and those, together with what were found after death, are preserved at Guy's Hospital. The case is described by Dr. Marcet, in the first volume of the *Medico-Chirurgical Transactions*.

When a person has taken a great quantity of chalk mixture, and even magnesia, concretions have sometimes been formed. There is a preparation in the Museum at St. Thomas's, where the intestines of a child are completely blocked up with magnesia: it has the appearance of hard mortar regularly cemented, and is said to be magnesia. It is therefore necessary to be on your guard, when you are exhibiting chalk, or magnesia, not to give it too long without ordering a purgative, so as to carry it away. There is a case on record of a person who had taken magnesia a long time, and suffered a great deal, and then suddenly discharged a large quantity of powder of magnesia from the intestines. Sometimes it is a fact that from magnesia or chalk the intestines become completely blocked up. The carbonate of iron will have the same effect. It is necessary, when you are giving this medicine in any quantity, to see that the bowels are regularly opened. You may give an immense quantity if you attend to that point. I related a case where a man took nearly two pounds of it every day for some days, when labouring under tetanus (of which he got well by-the-by), and he regularly discharged large lumps of carbonate of iron: they regularly came away, as they would from a horse, covered with mucus, and gave him no pain whatever; but then he had a clyster, to prevent any mischief. If a person do not attend to his bowels, a great accumulation may take place in the rectum, and the individual may be obliged to pick it out; but this must be bad management. I have known circumstances of this sort occur two or three times. I had another patient labouring under tetanus, to whom I gave this remedy, and he also got well; but if the nurses did not give him purgatives properly, he suffered pain in the rectum—the rectum was distended and became dry, and he was obliged to pick the iron out. A shovelful was found in his bed, which he had amused himself day and night in removing. I recollect an obstinate hysterical girl, and also the case of a lady, in whom a similar accumulation took place; but in these cases it arose from the patients' refusing to let us know the state of their bowels. It is right to know that if you do not pay proper attention, such things may occur.

Dr. Barlow, of Bath, mentions a case where sulphate of iron pills were discharged a year after they were taken. This is another general circumstance, shewing that articles may remain for a long period in the alimentary canal before they are voided. Substances which are liable to concreate should not be given unless you attend to the bowels. Dr. Prout told me that he was sent for, a year ago, to see a lady from whom some odd things had come away. She had suffered excruciating pain, and it turned out to be lark's bones. This lady had been in the habit of eating larks (some ladies are fond of larks), and she munched the bones. She was a lady of title, but in consequence of this lark-eating she suffered great pain. The discharge was sent to a celebrated chemist, at Tooting, in order that he might ascertain what it was. He first discovered it to be bones, and afterwards, from their figure, they were ascertained to be the bones of larks.

It was the fashion a few years ago (and I believe it is not yet quite out), for people to stuff themselves with whole mustard-seeds: they were thought to keep the bowels very open; some said it was a good practice, and others distributed pamphlets and tracts recommending it. Last year a gentleman came to me with various odd affections of the alimentary canal, which I could not well understand. Two days afterwards, he brought me a quantity of seeds that had come away, and I could not imagine what they were, till at last he told me he had been eating mustard-seeds, but had not eaten any for six weeks. He had given up the practice before he came to me, but they had accumulated in him, and actually remained for six weeks; and therefore his danger arose from that. We know that they generally come away whole. One gentleman told me that he sowed some after they had passed through him, and they produced just as good sallad as if he had not used them. Fashionable people have always some whim about them—they are always taking something; but I believe that the day of mustard-seed has pretty well passed by. Mustard-seed will accumulate just as other things.

In cows you very frequently find concretions of the alimentary canal, consisting of their hairs. They lick their hairs, a portion goes down with the saliva, and these concreate together into a hard ball. They are found not only in cows, but in many animals. Millers' horses are said to be subject to these concretions, from the grit of the stone-dust in the mills; and particularly, it is said, when they are fed upon bran. The poor people in Scotland, who eat oat bread, sometimes have conere-

tions of this description, formed of the beard of the oat. The outside of such concretions as these is like velvet.

It is found that the earthy phosphates are frequently mixed with hair, the beards of oats, or whatever else may have been swallowed and become cemented together by them and the mucus. Sometimes, instead of the phosphates being mixed up with the other ingredients, they form into a concretion around a nucleus, just the same as takes place in urinary calculi. The ammoniacal magnesian phosphates particularly will form around a nucleus of any sort. Sometimes the nucleus has been stale fruit, sometimes a piece of bone, sometimes a pin that has been swallowed, and sometimes a gall-stone. We shall see that it is the phosphates particularly that are formed around a layer in the urinary organs. In some of these concretions, oxide of iron, oxalate of lime, muriate of ammonia, and muriate of lime have been found. There was a lady who was said to discharge a large quantity of stones—specimens of which are on the table—from the urinary organs, but whether she was telling an untruth I do not know. A medical gentleman was attending her, and they wrote up to their friends to know whether they had seen such wonders. It was very singular that two ladies in different parts of the country discharged similar stones, and both cases happened to come within my knowledge. Whether there was any deception or not, we could not tell; but Dr. Prout considered that if there were not, they must have come from the intestines. There was said to be excruciating pain attending their discharge. The stones have the same appearances, and the same chemical qualities; they contain oxide of iron and phosphate of lime. Dr. Prout considered that many of these were too large to pass from the urinary passages, and that the nurse the patient stated she had voided must be incorrect. It is true that very large stones will pass through the female urethra, but they would have caused more suffering than she complained of in the bladder.

These gastro-intestinal concretions are sometimes, of course, very large. I recollect having read of the case of a woman in which they were found nearly as large as a hen's egg in the stomach. The same writer mentions finding out some, which weighed four ounces, in a soldier's stomach, and nine, which altogether weighed three ounces three drachms. In the colon of a young child one was found which weighed two ounces and a half, and was six inches long. The child died in consequence of it. In the Philosophical Transactions for 1686, there is an account of a woman who discharged many, varying in size from a

pea to a filbert, and that in two years she discharged five pounds weight. In the 32d vol. of the Philosophical Transactions, there is an account of a pregnant woman who discharged some that were very large; one of them weighed above two ounces. It is, therefore, a fact that such concretions do occasionally occur. Sir H. Sloane mentions a case where two hundred were said to be discharged.

These concretions are much larger in brutes than in human subjects, and also more common. In a brute one has been found weighing fifteen pounds twelve ounces. They chiefly occur in ruminant animals, and in slow-draught, and miller's horses, which are fed on bran.

Both in the brute and human subject these concretions are spheroidal or oblong; they take an imperfect polish, are more or less porous, and are radiated or have layers. I shewed you biliary concretions of both kinds—some were disposed in radii and others in laminae.

Those which are taken in small ruminant animals, such as the antelope or the goat, are called *bezoars*. The word is said to be derived from a Persian compound—*pa zahar*, meaning alexipharmic.

Bezoars were once so valued on account of their supposed alexipharmic properties, that one in the East has fetched, when very fine, six thousand livres, and has been hired in Holland and Portugal at the rate of a ducat per day. There are specimens on the table, but some of them are probably artificial, for being sold at a great price they were imitated. They were formerly sold at druggists' shops, and those before you I procured from an old druggist's. They are said to have concentric layers, and sometimes to be chrySTALLIZED. They will take a polish, and even have a metallic lustre. These have evidently been stained. Sometimes there is an accidental nucleus within, and they will rattle.

They are found to consist chiefly of vegetable matter, and some have an aromatic smell, from the circumstance of the animal having eaten aromatic herbs. It is said that it is only those which come from the West that take this polish; and that the Eastern have often a gloss of white. The mode of distinguishing the genuine from the spurious is said to be this: if you take a piece of paper rubbed over with chalk or lime, and draw a genuine bezoar across it, it turns it green, or of an olive colour; whereas, if it be spurious, the colour of the paper remains unchanged. However, the matter now possesses very little interest, since a belief in their virtue is no longer entertained.

Symptoms.—Concretions in the alimentary canal, if retained, give rise to violent vomiting, to violent gastrodynia, dyspep-

sia, colic, constipation, and to death. By the obstruction which they produce, you have all the symptoms of enteritis, colic, or strangulated hernia.

Treatment.—Of course the treatment, whether you know the nature of the concretion or not, is the same as for colic or enteritis; but as I said before, it is well to ascertain the state of the rectum. By passing a clyster up the rectum, you will have the means of learning whether the obstruction is situated there. Sometimes these concretions have reached the rectum before they have been stopped.

ENGLISH CHOLERA.

Having spoken of gastro-intestinal concretions, the diseases which I shall now proceed to consider will all be affections both of the stomach and intestines, and the first of which I shall speak is cholera.

Symptoms.—This disease is characterized by a sudden attack of bilious vomiting and purging. At first the discharge is sometimes thin and watery, and it has been called *white vomit*, but very soon pure bile comes away—in fact, unless there be a discharge of bile, it is not cholera. The disease is marked, besides this discharge of bile upwards and downwards, by severe pain in the abdomen, with very severe spasms of the abdominal muscles and calves of the legs, and in very bad cases even in the neck and back. There is no rigidity, as in tetanus; constant spasm, but violent contraction alternating with relaxation, drawing the muscles up in lumps. There is great anxiety and great debility; burning heat generally at the pit of the stomach; and as you may well suppose, from such a quantity of bile being poured forth, there is thirst and headache.

Progress.—These are the symptoms which we see every autumn in this country. At last, however, from this violent pain, and from this profuse discharge, the body becomes cold, great faintness is felt, perhaps there is actual syncope, the patient sinks, loses his power, becomes excessively weak, and then every thing occurs exactly as if hæmorrhage had taken place. General convulsions occur, the spasm ceases, and the patient dies as if he had lost an immense quantity of blood.

Duration.—This affection may last only a few hours (of course every body must have seen it seize persons early in the morning, and the parties be dead in the middle of the day) or it may last many days; and if it subside, it possibly may be followed by inflammation. I have frequently seen gastro enteritis take place after the discharge had entirely ceased.

Nature of the dejections.—The bile is generally found to be very acrid; and the vomiting and purging sometimes alternate,

so that the more the patient vomits the less he is purged, and *vice versâ*. Besides the bile discharged there is usually a great secretion of another fluid, no doubt from the stomach and intestines. The same state may occasionally arise from an overflow of the secretion of the mucous membrane of the stomach and intestines.

Connected with other disorders.—Intermittent and remittent fevers, and dysentery, in hot climates, very frequently begin as cholera; I might say, perhaps, with cholera.

Predisposing causes.—The disease is common in hot climates, and in mild climates in hot weather.

Exciting causes.—Cholera is particularly induced by sudden cold after long-continued heat, just the same as inflammation. It is observed that occasional falls of rain are particularly followed by cholera in hot seasons and hot climates. Dr. Macculloch ascribes this disease to malaria, and probably that is one of the causes; but various things will excite it. Violent passion, violent emotion of mind, will cause it. From the latter circumstance people are often vomited and purged, and sometimes both, and the discharge will be green, so that cholera is one effect of violent grief. Some persons have this from certain ingesta; any acrid substance may induce vomiting, may induce purging, or may induce both; and in this case the discharge may be of green stuff, and therefore it may be cholera.

Treatment.—The mode of treating this affection is, in the first place, to give plenty of chicken-broth, or any other diluent, so as to dilute the acrid bile which produces such unpleasant effects on the stomach and intestines. You should also exhibit large doses of opium, either the tincture or in a solid form; perhaps the latter would stay best on the stomach. It may be necessary, from the extreme weakness, to give brandy and other stimuli, and have recourse to the hot bath. The greater number of cases of cholera that we see, will do well if you give the patient warm diluents so as to dilute the bile, and let nature discharge it with as little irritation as possible to the stomach and intestines; but it is nevertheless advisable to lessen the disease at the same time, by exhibiting full doses of laudanum. But when the patient is weak, as in the case of hæmorrhage, then it may be necessary to have recourse to stimuli. Should the disease chiefly consist of vomiting, it may be desirable to send the bile downwards, and calomel will then be the best medicine; it stays better on the stomach than any thing else. An injection may be found very useful.

If the case be taken in time, and this mode of treatment adopted, it is very rare for patients to die. You have carefully to

examine whether there is any congestion in the head, or any inflammation. After a time these are very likely to occur, and it is necessary to treat them as you would under any other circumstances. After the disease it may be necessary to give tonics, and support the strength, or inflammation may come on; and it may be necessary to bleed. Sometimes after the affection the diarrhœa continues, and it may be necessary to check it in the usual way; but still it is necessary to ascertain whether it is accompanied by inflammation or not, for it very frequently is.

This is cholera properly so called; as to that disease which has so unfortunately received the name, and respecting which so much has lately been said, I shall speak of it next.

SOME ACCOUNT

OF

PROFESSOR EHRENBURG'S DISCOVERIES

Relative to the Structure and Functions of the Infusoria.

MANY readers will perhaps be surprised at the mention of the structure and functions of animals, the discovery of whose mere existence has been until recently deemed the ultimum of zoological research, and regarding whom the sum total of our knowledge has been hitherto confined to a few details on their external forms and active motions. Yet, in the midst of their transparent tissues, the German naturalist has, by a peculiarly ingenious method of observation, developed a highly-complicated organization, which, with those who arrange the animal kingdom in a linear series, will remove them far from the extremity of the scale. The existence of a digestive, muscular, and generative apparatus, is established beyond doubt; and organs have been also discovered, which bear great analogy with the vascular and nervous systems.

Before entering into the detail of the organization of the Infusoria, it is proper to state briefly the method by which the organs are rendered visible. This consists in furnishing the infusoria with organic colouring matter for nutriment. Simple as this may appear, it was not until after ten years' observations that Dr. Ehrenberg succeeded in selecting the fittest substances, and in applying them in the manner best adapted for the satisfactory exhibition of the phenomena. It was not until he used pure indigo that these experiments succeeded in a desirable manner. Immedi-

ately on a minute particle of a highly-attenuated solution of this substance being applied to a drop of water containing some of the pedunculated vorticellæ, (which are best adapted for the first observation,) and placed under the object glass of the microscope, the most beautiful phenomena presented themselves to the eye. Currents are excited in all directions by the rapid motions of the ciliæ, which form the crown round the anterior part of the animalcule's body, and indicated by the movements of the particles of indigo in a state of very minute division in different directions, and generally all converging towards the orifice or mouth of the animal, situated, not in the centre of the crown of ciliæ, but between the two rows of these organs which exist concentric to one another. The attention is no sooner excited by this most singular and beautiful phenomenon, when presently the body of the animal, which had been quite transparent, and bearing much resemblance in aspect to some of the marine Rhizostomæ, becomes dotted with a number of distinctly circumscribed circular spots, of a dark blue colour, exactly corresponding to that of the moving particles of indigo. In some species, particularly those which are provided with an annular contraction or neck, (such as the *Rotifer vulgaris*,) separating the head from the body, the indigo particles can be traced in a continuous line in their progress from the mouth to these internal cavities.

It is requisite in these experiments to employ colouring matter which does not chemically combine with water, but is only diffused in a state of very minute division. Indigo, carmine, and sap green, are three substances which answer very well the necessary conditions, and are easily recognized by the microscope. But whatever substance is used, we must be very particular that it contains no lead, an impurity which very frequently enters into the colours of commerce.

The microscope which Dr. Ehrenberg has used in all his investigations, is one constructed by Chevalier, of Paris: it possesses a power of 800. In very few cases, however, is it necessary to use this high power, and only to demonstrate the existence of an internal cavity in those species which do not exceed from 1-1500th to 1-2000th of a line in diameter, such as the *Monas termo*, *atomus*, and *lens*, and which almost elude the power even of so powerful an instrument. In almost all cases, a power of from 300 to 400 is sufficient; and Dr. Ehrenberg has made all his observations and drawings of the structure of the *Hydatina senta* with a power of 380.

In conformity with the great axiom of scientific observation, to measure every

thing which is capable of measurement, Dr. Ehrenberg has not neglected to express in numbers the dimensions not only of the totality, but also of the integrant parts of these beings, placed as it were at the verge of organized nature. For this purpose he uses a glass micrometer, constructed by Dollond, which gives directly the ten thousandth part of an inch, and permits of a much smaller quantity being correctly estimated, as it contains the astonishing number of 400 equal parts distinctly cut in glass within the space of half a line. By means of a micrometer screw, which has been since constructed by Pistor, of Berlin, he has been enabled to measure directly 1-48,000th of an inch, or 1-4000th of a line, a degree of minuteness which is never necessary in actual practice.

1. *Digestive System*.—By the use of colouring matter in the way above-mentioned, a digestive system has been demonstrated in all the genera of this class of animals, distinctly characterized by Müller. This fact Dr. Ehrenberg states in the following proposition:—"All true infusoria, even the smallest monads, are not a homogeneous jelly, but organized animal bodies, distinctly provided with at least a mouth and internal nutritive apparatus." In none has the cuticular absorption of nutritive matter ever been observed, which had been the opinion of all previous writers upon the subject, not from any positive observations, but merely from their inability otherwise to explain the nutrition of these animals. Generations of these transparent gelatinous bodies may remain immersed for weeks in an indigo solution, without presenting any coloured points in their tissue, except the circumscribed cavities above referred to; and when in a state of activity, the minute particles of indigo and carmine are seen to hurry rapidly over the whole surface of their transparent bodies, in order to reach the mouth, generally situate at one or other of their extremities. Indeed there is no necessity of having recourse to such a supposition, when we can clearly see the prehension of colouring particles, their reception into a mouth, and conveyance from thence into an internal stomach or stomachs.

The alimentary canal presents, as in the other classes of the animal kingdom, the utmost variety in respect to form, situation, and degree of complication. It is in the *Monas termo*, *pulvisculus*, and other larger monads, simply a round sac in the centre, and occupying the greater part of their bodies. In the genera *Enchelys*, *Paramacium*, and *Kolpoda*, it assumes the form of a long intestinal canal, traversing the greater part of the body, and at times convoluted in a spiral manner, which is furnished with a great number of cæcal ap-

pendages, or stomachs; this singular disposition, of which no other example occurs in the animal kingdom, is particularly distinct in the *Leucophrys patula*. That these blind sacs are real stomachs, and do not at all correspond to the cæca of other animals, is evident from the fact of their being filled with colouring matter immediately on its being received at the mouth, or anterior orifice of the canal. The tubes which connect these sacs to the main canal of the intestine vary very much, both in length and in diameter, as well among the different cæca, as in the same one at different times, being usually in a state of great contraction, and at times scarcely perceptible when the cavity to which it belongs is empty, and may be supposed not to be in a state of activity. We can count from 100 to 200 of these sacs in the course of the intestine of the *Paramacium chrysalis* and *aurelia*. When they are filled with colouring matter, the common intestinal tube is usually quite empty and transparent; this, joined to the bluish, reddish, or greenish tint, which they often assume when empty, may have been the reason that these sacs were mistaken by Müller for ova, and by Schweigger for internal monads still adhering to the parent trunk. In other infusoria, as the *Rotifer vulgaris*, the alimentary canal is in the form of a slender tube, and extending nearly the whole length of the body, and terminating at its anal extremity in a dilatation or cloaca for the reception of the ova and the male seminal fluid, previous to its termination at the surface of the animal. Others of larger dimensions, as the *Eosphora najas* and *Hydatina senta*, and in general all the natural group of the *Rotatoria*, possess a singular cavity of considerable size and oval form, situate in the anterior part of the body; the *Zygotrochis nudus* would seem to form an exception to the general rule of this division; for this animal, when filled with colouring matter, presents a slender, spirally convoluted intestine in the centre of the body. In this animal also, the posterior cloacal dilatation is enlarged into a considerable cavity, which can retain the colouring matter for some time previous to its being discharged by the anus.

The number of stomachs varies no less than their form. The whole tribe of the *Rotatoria*, as already observed, possess but a single cavity. In the *Monas termo*, four can be reckoned.

The number of sacs, which are so many distinct digestive cavities, although connected together by a common tube, varies from one and two hundred down to thirty-six in many *Forficellæ*. The largest number is in the *Paramacium chrysalis*, Müll., where it amounts to 120, and yet there is ample space for still more.

The *anus* is easily distinguished from the mouth, when the animal is filled with colouring matter, by its discharge from this orifice, in large irregular coherent masses, very different in appearance from the minute state of division in which it enters by the mouth. Its position varies exceedingly; in the greater number, such as the *Hydatina senta*, *Rotifer vulgaris*, and *Eosphora najas*, it opens towards the posterior extremity of the animal; in the first of these it is on the back. In the *Kolpoda cucullus* it opens into the concave surface of the animal, close to the mouth, from which it is only separated by a tongue-shaped eminence. In some of the spirally pedunculated vorticellæ, its disposition is very singular, opening along with the mouth into a common fissure, which is not situate in the centre of the circular ranges of ciliæ which surround the anterior extremity of the body, but towards the margin, between two of these concentric circles.

The *mouth* merits the notice of the systematologist, from the very precise characters which he can draw from thence for his subordinate divisions. This organ reaches its greatest complication in the *Hydatina senta*, where it consists of an orifice opening in the centre of a globular head, and provided with a pair of serrated mandibles, each resembling somewhat the single mandibles of some of the mollusca, such as the common *Helix pomatia*, or those of the *echini*. When the animal is in the act of taking its food, these mandibles are in perpetual motion, opening and shutting with great rapidity, to absorb the colouring particles brought within their reach by the currents excited by the motions of the ciliæ. This very singular organization is certainly one of the most curious phenomena visible in their whole structure, and is perhaps one of the most important, as shewing so close an approximation to animals far removed from them in the zoological series. Each mandible generally possesses five distinct teeth, but the number varies from two, three, as far as six. Dr. Ehrenberg has since succeeded in demonstrating their real nature, by the use of very fine folia of mica, (the whole animal is not more than one-eighth of a line in length,) and has come to the conclusion that they are separate, simple, hard bodies, enveloped with a fleshy covering, which are ingrained into one another like the fingers of the hands when joined.

The ciliæ play a very important part in the economy of this class of animals. They may be considered as the principal organs of taste, of touch, and of propulsion. When the animal is at rest, they are often quite imperceptible, but on the addition of a small proportion of colour-

ing liquid to the drop of water, they become very apparent, being in a state of great activity, seeming to be the principal agents by which they excite those currents which afford so beautiful a spectacle under the field of the microscope.* In the *Monas pulvisculus*, and other larger monads, their number amounts to 10 or 20, and we may from this conclude that they exist even in the smallest monad. They sometimes surround the mouth in a single row (*Vorticella convallaria*, *Rotifer vulgaris*), sometimes in a double row (*Vorticella citrina*;) occasionally they extend in regular lines, or are irregularly dispersed over the whole surface of the body. The former disposition occurs in the *Leucophrys pyriformis* and *patula*, the latter in the *Actinophrys sol*. They occupy, in other cases, only one side of the body, (*Kolpoda cucullus*.)

An *œsophagus* can only properly be said to belong to those which, like the *Eosphora najas* and *Hydatina senta*, possess a notable contraction between the mouth and the stomach. This is especially distinct in the latter, where I have distinctly traced the passage of individual coloured globules along this narrow canal from the mouth into the intestine.

Perhaps this is the most appropriate place to notice an organ of a very obscure nature, which Dr. Ehrenberg dignifies with the name of a pancreas. It is in the form of two kidney-shaped, grayish-white, glandular-looking, transparent bodies, which are placed on each side of the upper extremity of the intestine, firmly connected to, and closely embracing it. Dr. Ehrenberg regards them as bearing a greater analogy to the pancreas than to the liver of the higher animals, from their colour, form, and connexions. They must, however, be left to further inquiries.

2. *Muscular System*.—A fibrous muscular tissue being the proper agent of all voluntary contraction in the animal kingdom, we might, *à priori*, expect its existence in the class of infusoria, which are so remarkable for the rapidity and energy of their movements of propulsion and translation. In the former they can only be compared with fishes, and in the latter with insects. Contractility of tissue can never explain those active voluntary efforts by which they avoid obstacles when swimming in myriads in a single drop, convey the nutriment towards the mouth, and perform the act of deglutition. Previous, however, to

* One of the most favourable moments for seeing these ciliæ to advantage, particularly in those species in which they invest the whole surface of the body, is when the drop of fluid under the microscope is nearly dry, when they may be seen elongated to their utmost, in a state of great activity; or if the animal be nearly expiring, in a state of rigid erection.

Dr. Ehrenberg, nothing like the muscular fibre had ever been attempted to be shown in these animals.

As yet, from their extreme tenuity, no distinct fibres have been detected in the second and more minute division, styled by Cuvier *Homogeneous infusoria*, and in the new system of Dr. Ehrenberg, *Polygastrica*; although, from their extremely vigorous contractions, as well as from their presence in the division of the Rotatoria, we are entitled to infer their existence. In this last, distinct fibres are perceptible in the *Eosphora najas*, *Rotifer vulgaris*, *Philodina erythrophthalma*, and *Hydatina senta*.

We shall select the muscular system of the latter, the *Hydatina senta*, as a specimen, from its greater distinctness and complexity. The perfectly transparent gelatinous body of this animal, when seen through the microscope with a power of 380, appears to be traversed longitudinally by several narrow bands of fibres, perfectly transparent, and of a greyish white colour. When the animal throws itself into its violent lateral contortions, these fibrous bands are observed to shorten, become broader and thicker, (from their slightly diminished transparency,) on the side towards which the contractions are made; and on the convex to become so extremely elongated and attenuated as to be almost, in some cases quite, imperceptible. The real muscular nature of those organs, and that they are the real agents in effecting the motions of the animal, is thus placed beyond all doubt. These muscles never lose their apparent state of tension, which they would undoubtedly do on the contractions of the animal, if their nature was of another description; and when the two extremities of the body are equally approximated to each other, none of the bands become invisible, but all increase to nearly twice their former breadth, with a corresponding diminution of their transparency.

The envelope of the body of the hydatina consists of a double transparent membrane, the two layers of which are in contact with, and scarcely distinguishable from, each other, when the animal is in a state of repose. But, upon the contractions of two or more of the muscles, the internal membrane into which they are inserted becomes separated to a greater or less distance from the external. During the whole of these phenomena the stomach, ovaries, and the whole of the viscera, are perfectly visible through the transparent muscles.

These principal muscles are four pairs, which take their origin from the opposite ends of the animal, and proceed in a radiated manner to be inserted by broad striated bands near the middle of the body, (between the fourth and fifth pair of twigs

given off from what Dr. Ehrenberg calls the great dorsal vessel.) The four upper or anterior muscles rise by narrow insertions from the junction of the head with the body at the root of the rotatory organs; the four posterior or inferior, from the point of insertion of the bifid tail into the body. The extent of insertion of these muscles is much greater in the *Eosphora*, *Philodina*, and *Rotifer*, than in the *Hydatina*; in them it reaches at least from the second to the sixth of the above-mentioned transverse twigs.

These great longitudinal muscles are distinct to the most unpractised eye, but Dr. Ehrenberg views as of a muscular character, 1. The seventeen sections of the rotatory organ in the *Hydatina*, which must be the principal agents in directing the motions of the ciliæ; 2. A contraction or sphincter near the extremity of the cloaca; 3. A striated organ behind the cloaca, which he considers, from its situation, as an accelerator of the seminal fluid, a *musculus ejaculatorius*. In none of these, however, except the last, can the existence of a fibrous tissue be considered as beyond a doubt; though, from their situation, it is more than probable that this is their true nature. All of these parts seem to be attached to the inner layer of the external double membrane, and to be unconnected with the subjacent viscera. It is not improbable that the tail may possess some proper muscles, as its motions are not performed laterally in common with the trunk, but by an alternate retraction and elongation.

3. *Generative System.*—The partizans of the *generatio spontanea vel primitiva*, who so long stood their ground in the class of Entozoa, after being forced to relinquish this position, by the discovery of the ova of these parasitic animals, took refuge in the darkness and obscurity of the microscopic infusoria, where they were almost secure of an undisturbed possession, while there was nothing known concerning them except as a homogeneous mass of transparent jelly, endowed with a few active motions; and where their negative arguments could only be attacked by analogical reasonings.

The observations of Dr. Ehrenberg have not only given an additional extension to the great principle of Harvey, *omne vivum ex ovo*; but have, by a connected train of ocular demonstration, proved the existence in this class of the whole three species of generation—the viviparous, the oviparous, and the gemmiparous, and even of the simultaneous exercise of two of these in the same individual, at different epochs of its existence. Waiving at present the corroboration which this might give to the view of infusory animals forming a pa-

parallel series to their more apparent prototypes, let us proceed to state shortly a few examples of each of these varieties.

In the interior of the *Rotifer vulgaris* we often see young animals of a diminutive size, (that of the parent varying from $\frac{1}{4}$ th to $\frac{1}{2}$ th of a line,) perfectly formed, and near the period of exclusion, which already possess the two red points, (eyes,) near their anterior extremity, and a distinct mouth and head. They assume various postures in the interior of the parent trunk, being at times coiled up in a spiral form, or extended to their whole length. These same foetus, if we may so call them, Dr. Ehrenberg has seen excluded in a living state from the parent. All the individuals of the *Hydatina* are hermaphrodite, possessing the completely formed male and female organs. The female consist of an ovarium, which, when in the unimpregnated state, is an oval perfectly transparent bilobed bladder-like body, closely embracing the lower part of the intestinal tube. When in an impregnated state, it increases very much in size, being augmented by the addition of two or more oval appendages, so that the whole mass fills the greater part of the posterior half of the body of the animal. When quite ready to burst, it assumes a greenish grey colour. These rounded bodies communicate by a canal, scarcely perceptible in the unimpregnated state, broad and distinct when nearly ripe, with the cloacal dilatation formerly noticed as existing near the anal orifice of the intestine. That the ova are not internal germs, an opinion entertained by many older observers, such as Lamarck and others, is proved not only from the above-mentioned development and connexions of their containing vesicles, but also by the distinct existence of the three substances which, in the ova of the Entozoa, M. Rudolphi considers as the chorion, allantois, and amnion. In the centre of many ova, there can be recognized a darker point, which is either the embryo, or cicatrix in which the latter is developed.

The adult *Hydatina* possesses, besides, two organs which Dr. Ehrenberg considers as the male organs of generation, but the real nature of which is a little more doubtful than that of the preceding. They resemble very much in form the milt of fish, consisting of two elongated bodies, extending nearly the whole length of the animal, exterior to the ovaria, broader towards the head, diminishing towards the tail. They terminate (a strong corroboration of this view of their true nature), in a number of spirally convoluted tubes, which finally open by two separate canals immediately behind the oviduct. These spiral convolutions are enveloped by an organ of a very singular nature, the function of

which is very obscure; it is oval, transparent, remarkable for its irritability and sudden changes of form; at one time swelling out into a vesicular form, at another contracting into a small glandular-looking organ. Dr. Ehrenberg at one time considered it to bear some analogy to an uterus, but it is more probably connected with some office in applying the seminal fluid to the ova previous to the exclusion. This organ is wanting in the *Rotifer* and *Philodina*, where the male apparatus otherwise resembles very closely that of the *Hydatina*.

4. *Vascular System*.—The existence of a digestive, a muscular, and a generative system of much complexity, and very far from what we might consider as their simplest expression, may now be viewed as an ascertained fact with regard to infusory animals. The existence of the two systems which remain for our attention, viz. the vascular and nervous, is as yet somewhat problematical. The organs on which Dr. Ehrenberg confers these appellations, are very apparent, but much doubt exists with regard to their real functions.

What has been denominated a vascular system is distinctly visible only in the *Hydatina senta*. Traces of a similar arrangement are now and then perceptible in the *Eosphora*, in particular positions of the animal, but they quite disappear when the integuments are in a state of strong tension. In the former, a series of transverse lines of a white colour, and inferior transparency to the rest of its body, succeed one another at regular intervals, from the head towards the tail. These transverse striæ might at first be taken for muscles, but they differ from these entirely in their aspect and connexions. They are nine in number, exactly parallel to, and nearly at equal distances from, each other. At first sight they seem to be complete rings encircling the whole body; but, upon a closer inspection, they are observed to diminish in breadth, and finally vanish on approaching the inferior or abdominal surface of the animal. On the contrary, they augment in diameter towards the back, where they all terminate at right angles, in a line, of an exactly similar appearance to themselves, running in a longitudinal direction from the head to the tail. This longitudinal line or vessel is nearly twice the calibre of any of its tributary transverse twigs.

It will be observed, that the disposition of this main dorsal trunk, with its collateral branches, is almost exactly that of the vascular system of the *Ascidia*, so beautifully demonstrated by M. Savigny, which is a strong argument for their being of the same character. No motion of an internal fluid is discernible in their interior, nor has any pulsation analogous to

a heart been ever observed. Both these phenomena, which would decide the question as to their true nature, Corti asserted that he had observed in the *Rotatoria* and *Brachionus*, but he was deceived by the tremulous motion of the canal leading from the mouth to the œsophagus. The same was the case with Gruithuysen, who mistook the motion of the intestine in the *Paramacium aurelia* for that of a sap-like fluid. It is worthy of note, that these white striæ are attached to the internal, not to the external tunic of the integuments.

5. *Nervous System*.—This name is given to a series of six or seven round glandular-looking grayish bodies, which envelop the upper or dorsal part of the œsophagus of the *Hydatina*. They are closely connected together, and are distinguished from all the other viscera of the body by their darker tint. The uppermost of these bodies (ganglia), or that situate in the mesial plane, is much larger than the rest, and gives off, from its apex, a slender branch, which proceeds upwards towards the integuments at the back of the neck, a little before the second pair of vascular twigs, where it forms a slight enlargement (ganglion); it does not stop here, but returns back and unites again, not with the large ganglion from which it was originally given off, but in one of the adjacent smaller ones. A complete circle is thus formed, bearing some resemblance to the nervous circle which encircles the œsophagus of the mollusca, except that in this case the whole circle is situate on the dorsal or upper side of that canal. From the point of contact of this nervous circle with the dorsal vessel, it gives off two very slender twigs forward to the anterior part of the head, where, in other forms of the *Rotatoria*, such as the *Rotifer vulgaris*, the two red points (eyes) are situate. In some, such as the *Eosphora najas*, a single large red point is situate on the back of the neck, in the exact position of the ganglion at the apex of the circle*. The above-mentioned large mesial œsophageal ganglion (brain), sends off posteriorly another branch of much larger size, backwards along the abdominal surface of the animal, which closely adheres to the internal layer of its double envelop.

That these different filaments and ganglia, to which we have given the name of nerves, are not muscles, is evident from their form, their mode of insertion into the integuments, and because, in the contrac-

tions of the animal, they are not shortened, but assume a serpentine form, being apparently quite passive. They are not vessels, because no pulsation nor motion of a contained fluid has been hitherto perceived through their transparent tissues. If they are not organs of an entirely unknown nature, the whole analogy of their form and position, compared with the nervous system in other invertebrate animals, favours the idea of this being their true nature.

We may here consider, as appendages to the nervous system, those coloured points situate in the anterior part of the head of these animals, and most usually on the dorsal surface, which have been considered as eyes. As already noticed, the first discovery of these organs was made in 1816 by Nitsch, who saw in the *Cercaria viridis*, (now referred by Dr. Ehrenberg to the genus *Euglena*), three black scaleiform points. In the *Rotifer vulgaris*, their pigment is of a red colour, and they are three in number, two small ones at its anterior extremity, and a single larger one at the nucha, in the situation of the apex of the above-mentioned nervous circle in the *Hydatina*; and it is very probable that the two filaments, which, in the latter animal, are sent forwards from this ganglion, or even the ganglion itself, subserve the purposes of vision. The number, disposition, and colour of these points, are the same in the *Eosphora najas*, where the mesial eye is still larger and more distinct. In the *Philodina erythropthalma* their colour is the same, but they are only two in number, (the most common disposition in this class,) much smaller, and situate more posteriorly. In the *Lepadella ovalis*, one only is visible, of considerable size, in the mesial situation of the large one of the *Eosphora**.

NEW FORMS OF SPLINTS FOR THE EXTREMITIES.

By JOHN GRANTHAM, Esq.

[Continued from p. 532, *ante*.]

HAVING in the former part of this paper described the splints for the upper extremities, I shall now proceed to those intended for the lower.

FIGURE I

Is intended to represent an apparatus for fractures of the os femoris, one of which I presented to Mr. Lawrence in 1829, who gave the following descrip-

* The best view of the disposition and appearances of the œsophageal ganglia is from the dorsal side of the animal, in a line with the great dorsal vessel. The nervous collar given off from the brain is, however, best seen on a lateral view.

tion of it in his Lectures, as reported in the *Lancet* of 1829-30, page 317. He says, "What I now show you is a contrivance of this kind [speaking of double-inclined planes], to which a strap or band, calculated to fix the pelvis, is attached. You observe that a double-inclined plane is here obtained for the lower extremity, this part being adapted to the thigh, and this part to the leg. You will understand of course that when an addition of this kind to the bed is used, pads are placed over the wood, in order that the limb may lie easily. You will see that this apparatus is so contrived, that if care be taken, it presents a greater or lesser angle at the edge which corresponds to the ham; and that part which corresponds to the thigh is so constructed, that its length can be increased or diminished at pleasure, so as to accommodate the board to different individuals. In the first place, the length of the part on which the thigh is

to rest, must correspond exactly with the length of the sound limb, the apparatus for which underneath enables you to lengthen or shorten the various parts, and is very simple. Then the foot-board (*b*) can be placed at appropriate distances by means of the holes which you see in the lower parts, so as to make that part correspond with the exact length of the leg. The lateral pegs may be of use to retain the leg in any one part. Then the other end facing the posterior part of the thigh, fixes against the tuberosity of the ischium, and this band (*c*) goes round the pelvis, to keep that part of the body steady. There is another band (*d*) used for the purpose of fixing the other portion of the thigh; so that as far as it can be accomplished by this instrument, you render the thigh, the leg, and the pelvis, fixed*." But in this sketch there is a groove (*a*) con-

CASE OF PURPURA HÆMORRHAGICA.

To the Editor of the Medical Gazette.

SIR,

I CONSIDER it a duty to communicate to you a case of purpura hæmorrhagica, in which less difficulty was experienced in the treatment than usual, and which terminated rapidly and favourably.

A young woman, about 24, applied to me a short time since for a severe hæmorrhage from the fœces; her skin was also thickly spotted with petechiæ, and marked with intervening vibices; the tongue was brown, and the pulse was weak, so that further depletion appeared inadmissible. Carbonate of ammonia was given; but with no good effect on the hæmorrhage nor petechiæ. Aware of the effect of the action of vomiting on the venous circulation, which it appears to excite in a high degree, I directed half a grain of tartarized antimony to be taken every quarter of an hour in a little water, till vomiting should be produced. The result surpassed my expectation: immediately after vomiting the hæmorrhage ceased; from that time the petechiæ and vibices were gradually and rapidly absorbed, and the young woman recovered her usual health without the repetition of the emetic or the employment of any other remedy.—I am, sir,

Your obedient servant,

R. P. PLAYER.

Malsbury, July 22, 1833.

ON THE TREATMENT OF BURNS.

To the Editor of the Medical Gazette.

SIR,

It is now considerably more than twenty years since I completely changed my mode of treating burns, having found from extensive experience, that the plan then in general use was almost constantly attended with no benefit, and very frequently with evidently bad consequences; and I then intended to communicate to the public the plan of management which I adopted, and have since uniformly found attended with the most undoubted beneficial effects. At this period, however, Dr. Kentish's plan of treatment made its appearance, by which, together with some publications that soon followed, I concluded, that the practice I meant to recommend was in a great measure anticipated; for although they did not exactly coincide, still they made so near an approach, that only a little more experience was required to make them perfectly agree, and to be introduced into general practice. The result, however, I am sorry to say, has not only disappeared, but the breach seems gradually extending, and the treatment of the most distressing of injuries is nearly as discordant as ever. This retrograde consequence, as retrograde it certainly appears to me to be, can only be accounted for from the apparently very opposite state of cause and effect to the method of cure proposed, and to the singularly unintelligible theories with which the new plan of treatment was supported, for certainly had it been left to the only fair way of deciding the merits of any practice—experience, the plan would have long ago become universal, and the public would have had great benefit conferred upon them; as, from the very frequent occurrence of such distressing accidents, the most urgent necessity exists for adopting any plan that can afford relief.

It seems quite superfluous for my present purpose to enter into any detailed account of the different *rationes medendi* which were brought forward in support and confutation of the new practice: they only require to be mentioned, that their importance may be understood.

Dr. Kentish supported his introduction of turpentine and other resinous

substances for the treatment of burns, by the principle of what he terms unity of action; namely, "that any part of the system having its action increased to a very high degree, must continue to be excited, though in a less degree, either by the same stimulus which caused the increased action, or some other, having the nearest similarity to it, until by degrees the extraordinary action subsides into the healthy action of the part."

Upon the above theory, Professor Burn observes, "It has been said that a burned part almost immediately sinks into a state of debility from the temporary action of an excessive stimulus, and the system being apt to sink along with it, and that by applying another powerful stimulus as a substitute for that heat which produced the burn, the action of the part would be supported, and the sensation lessened. This, I fear, was an opinion founded rather on the notions of Brown, than on the ground of experience." Again, the same author observes, "We know that turpentine applied to sound skin inflames it, and *a priori*, we should expect a higher degree of inflammation to be produced, if it were applied to a part already inflamed. What should be the effect of turpentine if applied as a dressing to a common blister, if the cuticle were peeled off? should it not be frantic agony, perhaps followed by sloughing of the part; and why should not the same effect result from it, if applied to a part inflamed, blistered, and peeled, after the application of boiling water? Experience is decidedly against the use of turpentine, or any strong stimulus, in all cases where the skin is not disorganized, and that, whether the extent be great or small, and whether the cuticle be entire or peeled off. The strong stimulus of turpentine can only be borne when the skin is partially torrefied, and nearly insensible. In such cases, the parts being nearly or altogether dead, it is not to be expected that any stimulus can give pain or do good; yet these, perhaps, are the cases most likely to be brought forward in favour of turpentine. In this extreme degree of torrefaction, it is then a negative application, or may be said to do neither good nor harm. This view, which I believe observation will prove to be correct, will confine the use of turpentine to such cases where the skin is not altogether destroyed, or

where it is neither acutely sensible, nor devoid of sensibility—of course within very narrow limits, and even within these, its recommendation may be rather negative than positive."

Again, the same author goes on to observe, "The result then of these general observations is, that the treatment of small and of extensive burns must in some respects be different. In the former, almost any plan may be adopted with safety, whether attended with relief or not; that is to say, the part shall heal if we merely avoid doing positive mischief, although we fail to do actual good. This is especially the case when there is only erythema, which will go off, whether we apply cold water or strong spirits, or wrap the part in cotton, or anoint it with salad oil, or bathe it with herring brine. But, in the latter, we can neither use the cold nor the stimulating plan to any degree; for the first must produce unusual coldness, and the latter, on its primary operation at least, excessive additional excitement, as cannot be otherwise than detrimental."

Mr. Samuel Cooper observes, "Dr. Kentish's theories are, as far as I can judge, visionary; they may amuse the faucey, but can never improve the judgment; they are nearly unintelligible; they are unsupported by any sort of rational evidence, and as being the dreams of a credulous sportive imagination, must soon decline into neglect, if not oblivion."

Dr. Thomson says, "that where the parts are destroyed and converted into sloughs, it does not matter much whether vinegar, oily liniments, turpentine, spirits of wine, or emollient poultices, are applied."

When these extracts, &c. are attentively considered, they clearly evince the melancholy situation of the treatment of the most distressing accident which can befall the human body; and it is really difficult to comprehend what is the plan these gentlemen would either themselves adopt or advise others to follow, so as to conduct such distressing occurrences to a pleasant termination: and while they seem all anxious to condemn that of Dr. Kentish, which we shall afterwards designate the stimulant, or more properly the warm digestive plan, still they neither recommend the old or the new, and propose distinctly no other. Indeed their objections seem to

have no other foundation than supposition; for as far as I can observe, none of these gentlemen speak from experience, and surely here, as in all other cases, we are not entitled to condemn any practice but upon such a foundation; and I must be permitted to observe, the logic of Dr. Burn, where he more than insinuates that if a burn shall ultimately heal (or, of course, any other disease shall not end in the death of the patient) it is of little or no moment what way you manage its treatment, so as to obtain an easy, expeditious, and perfect cure, appears to me singularly curious. For myself I shall candidly confess, that during nearly one-half of my professional experience, I continued to treat burns in the manner then in general use—viz with cold, oily, and sedative applications; but the result, if the case was only a scald, the cure was tedious, accompanied with much pain, and frequently ended in sloughing or ulceration, and the only relief that could be given was from the use of poultices; which, when they had at last brought the injured part to the state in which we were accustomed to treat other ulcers, a cure was effected with great difficulty, pain, loss of time, and a disgusting cicatrix. Nay, if the use of poultices had been prohibited as an application in the former treatment of burns, I really believe that it would not have been possible to effect a cure in any case whatever. It was from the uniformity of such unpleasant consequences that I resolved to alter my mode of treatment; and I no sooner had recourse to the resinous or turpentine ointments, than the most pleasant effects followed, and if I was called in immediately after the accident, not only was all pain almost immediately removed, but every chance of ulceration and sloughing, even in very severe cases of scalding and slight timefaction, prevented; the cure was speedy; with, in many cases, not even a cicatrix or blain observable. Indeed, so strong was my conviction of the good effects of this application, that I persuaded every family under my care to have a constant supply of Ung. Resinos. Com. in the house; and it has frequently happened, that not only mere scaldings, but burns from flame, melted lead, oil of vitriol, and gunpowder, have been all speedily cured, without coming to ulceration or leaving a mark of any kind.

Although it appears to me of very little importance whether or not we can establish the use of resinous or turpentine applications upon what may appear satisfactory principles, being completely satisfied that if any one will have recourse to these applications in the treatment of burns, they will at once fall in with and adopt the practice, still I beg leave to offer the following observations, as an attempt to account for their very beneficial operation.

The effects of mere scalding, or the more extensive injuries inflicted by heated matter, are the destruction, to a greater or less depth, of the surface to which they have been applied; and this event will be more or less extended, from the effects of succeeding inflammation, and which inflammation is sure to succeed the injury of burns if the pain and irritation consequent upon such accidents is not immediately subdued, or if they are long continued from improper treatment.

Every medical practitioner of experience must be well aware, that in the management of many cases of superficial inflammations, nay, indeed, of many internal ones, cold, sedative, inactive, or repelling applications, not only afford no relief, but are followed with great increase of pain and irritation, and even constitutional derangement: the inflammatory action is continued, and the parts, after a tedious progress, end in gangrene or sloughing. Examples of this occur in affections of the mammae, in erysipelas, in anthrax, whitlow, and other violent inflammatory tumors; also in cases of frost-bit chilblains, bunions, and corns. But the bad effects of such cold repelling inactive applications, would be particularly observed and felt in the management of the throat in angina maligna, scarlatina, &c. and very remarkably so in the treatment of blisters, if they had been applied in such diseases. In short, the mode in which these warm digestive applications act, and produce their beneficial effects in burns, may be easily understood from what we all know of the advantages obtained from poultices, not only as applicable to the treatment of burns, but of other local affections. They prove the very best discutient, if had recourse to in time, merely by relieving pain and irritation, from their warmth and their oleaginous lubricating quality: the tension and swelling ceases

to exist, and the vessels and general structure of the part affected are allowed an opportunity to regain their healthy state. That this is the true explanation, we find in the fact, that if the poultice becomes cold and dry, all the unpleasant symptoms immediately return, and we are frequently obliged, in order to bring the affection to a proper and speedy termination, to have recourse to making the addition to the poultices of the very applications recommended by Dr. Kentish; and whether we say with the Doctor, "that any part of the system having its action excited to a very high degree, must continue to be excited in a less degree, until the extraordinary action subsides into the healthy action;" or what appears to me rather more intelligible, that such warm digestive applications are always found to relieve burns, and other affections similar to burns, by relieving pain and irritation, and of course diminishing tension and inflammatory action, the natural structure of the part is gradually restored, the parts injured to a very considerable extent are absolutely preserved, and no unpleasant cicatrix or contraction follows; and what is still of very great and paramount importance, even in the most severe and extensive burns, the intense and horrible distress, however the case may terminate, is almost immediately and completely relieved.

But farther: when we attend to the various means which have been of late years suggested for the treatment of burns, we find that those which have the greatest character are all to be found capable of acting upon the principles of Dr. Kentish's resinous applications; viz. the use of cotton, spirits, Larrey's saffron ointment and styrax; and even Oglehorn's vinegar and chalk may be so explained.

In proceeding to detail the practice which I have uniformly found attended with the most immediate and beneficial effects, I may observe that the injury of burns has been generally divided into three heads: first, merely scalding of the cutaneous texture; secondly, attended with separation of the cuticle; and thirdly, when the substance of the cutis is either immediately or subsequently destroyed, and an eschar produced; and in almost every author who has advised the treatment of burns, a different mode of management has been recommended for each extent of injury, ex-

cepting by Dr. Kentish himself, and it is here I perfectly agree with the Doctor; and it is here also, perhaps, that the use of the same means in all the different extents of injury, has given the appearance of an absurdity to the practice, and thrown it into so much discredit as not only to check but even to discard its use, however strikingly beneficial it might have been found if only tried: and whether or not what I have already submitted shall be sufficient to remove such seeming contradiction, I trust, at all events, it will be sufficient to procure for the practice a fair trial.

The danger arising from burns, whether it is a scald or torrefaction of the part, entirely depends upon their extent, and also, in a certain degree, upon the constitution of the patient. If the case shall be that of the whole body being immersed in merely boiling water, and instantly extricated, I think it possible for a recovery to take place; but if its application shall exist for a minute, I am of opinion, from what I have seen, it must terminate speedily in death: but if the immersion shall be in boiling oil, brewers' copper, boiling seawater (as in the making of salt, &c.) then, I apprehend, however short their application may be, there is no hope that the poor sufferer can survive a very few hours.

The symptoms which take place in such cases, are an immediate shivering, or rather trembling and shaking of the whole body, attended with a singularly depressed and anxious countenance; oppressed and quick respiration; a rapid, small, and what many would deem a weak pulse; excessive pain and anguish—the wretched sufferer presenting altogether rather an appearance of agitation and confusion than stupor or excitement; and after continuing in this state for a very few hours, death comes to the relief of the miserable patient. But if the application of those boiling fluids (but more especially boiling water, or those nearly approaching to it) is under a minute, and only one-third of the surface of the body injured, I should be inclined to give a favourable prognosis; but, on the contrary, if the application of the heated body has been so long as that it must infallibly terminate in suppuration, then the probability of a fatal termination is much increased, and both the constitution of the patient and the supply of cordials and nourish-

ment, must also be taken into consideration.

In cases of torrefaction, which, from their extent and severity, must necessarily end in death, the symptoms and prognosis differ. There is a total absence of shivering and shaking; the pulse is neither so rapid, small, or apparently feeble, but rather has more of the appearance of a real inflammatory action; there is frequently considerable stupor, coma, and torpor; and here the patient does not sink so rapidly, but his existence is generally lengthened to twenty-four or thirty-six hours. Like the cases of a burn from liquids, the prognosis must be regulated by the extent and severity of the injury, but more caution is necessary, as all such accidents must be followed by extensive suppuration, and of course the consideration of all concomitant circumstances carefully kept in view. And with regard to the probable result of both these species of injuries, if the patient shall survive the first forty-eight hours, I then consider he has surmounted the danger arising from irritation, &c. and his case remains to be considered as what is likely to follow from an ulcerated surface.

Whatever may be the cause, extent, and severity of the burn, I instantly (if existing circumstances render it practicable) dress it with a thick-spread pledget of ung. resinosum, having a greater or less proportion of resin in it; and for which purpose I have been in the habit of keeping in the laboratory basilicum of three different proportions of resin. The ointment is spread on any kind of stuff most convenient. This dressing is only allowed to remain on for eight hours, if the burn is severe or approaching to torrefaction; but if it is only to the extent of a scald, then I allow it to remain twelve hours: the length of time, however, is regulated by the absence of pain; for if it returns, the application should be immediately renewed. The strength of the resinous ointment used, is to be regulated by the severity of the injury; in all cases of mere scalding, the mildest ointment will answer every purpose, but if otherwise, the others may be used accordingly; and in all cases short of torrefaction, it will not be necessary to use the strongest. These dressings are to be gradually reduced in strength, according to existing circumstances; if the injury is a mere scald,

the strength of the ointment may be weakened at the third dressing, and by the third day no farther dressing will be necessary; but if the scalding has been followed with peeling of the cuticle, then the resinous dressing must be gradually reduced, even below the third proportion of resin, by mixing it with lard, or simple cerate, when a cure will be effected in a few days, without pain, cicatrix, or much discoloration; but if the cure is improperly conducted, or, what is extremely common in the general practice of treating burns however slight, ulceration will take place, accompanied with some sloughy, elevated, and reflected edges, and great pain, uneasiness, and irritation. In whatever circumstances of burns these symptoms take place, they cannot be made to heal until they are brought to the state of a clean healthy ulcer; and for this purpose nothing will succeed but mild digestive resinous ointments, always, however, taking the greatest care that these applications shall be only applied to those parts of the ulceration which have the appearances now described, and they must be no longer continued of the same strength after these symptoms have ceased to exist; nay, indeed, the strength of these digestive applications should be as nearly proportioned as possible to the extent of these appearances; for if the change in the ulcer is attempted to be produced too rapidly, or if the strength of the dressing is continued too long, then the greatest pain and irritation follows; and although these symptoms may be relieved by change of dressings and poultices, still a strong tendency to fungous and luxuriant granulation follows, forming one of the most common and troublesome attendants of burns. It frequently happens, too, that these appearances in ulcerated burns occur more in one place than in another: the dressings must then be managed accordingly, for from the improper application at one part, the whole ulcer will be thrown into a state of irritation, the unpleasant symptoms reproduced, and the cure very seriously retarded.

If the application of the heated body should be followed by vesications, I never open them, but at the end of three or four days, when every unpleasant symptom has terminated, and the parts underneath may be supposed to have nearly regained their original state, I slightly puncture them with a needle, and repeat

the puncturing every day, so as gradually to discharge the whole of the fluid, when the surface underneath will be found perfectly whole.

It must now be observed, that however singularly beneficial resinous dressings may be in the treatment of burns, still their application in the most severe, extensive, and of course most dangerous cases, cannot be obtained; but in such situations, the most speedy and effectual way is to put the whole body, or the whole of the parts injured, into a warm bath, or to keep it moistened with cloths dipped constantly in warm water, which will be required to be heated at least from 106° to 110° , until proper dressings can be procured; and for this purpose a resinous dressing may be readily obtained by melting a sufficient quantity of oil, resin, and tallow or lard together into any convenient vessel, when the whole injured parts may be easily smeared over with it, by using a bunch of feathers, and this renewed as often as the pain returns, by which means the danger of immediate death may be avoided, the misery of the poor patient much mitigated, and perhaps his life preserved, more especially if the injury is merely scalding; but even although the burn is of a nature that allows little or no hope of saving the life of the patient, still much is gained if we can place him in comparative ease and diminished misery; nay, if by such means we can keep him alive for 24 or 48 hours, it is obvious we give him the only chance of final recovery.

The opinions formed of the effects produced upon the system in general, and the mode of treatment, are nearly as discordant as the local practice, the antiphlogistic plan being strongly recommended by some, while the stimulating and strengthening is equally enforced by others. The symptoms of rigors, convulsions, rapid breathing, and frequent pulse, being ascribed to the extravasation of fluid on the chest from sympathy with the surface; while the stupor, coma, &c. are ascribed to its effect upon the brain. I apprehend, however, it is quite superfluous to call in any other aid to account for the phenomena now mentioned, but the excitement produced in the brain and nervous system from the pain and irritation produced by the burn. Still the effects of mere scalding, and those of severe cases of torrefaction, are widely different; for it is only in the last instance, that

stupor and coma occur, the symptoms of convulsions and rigor are wanting, while the pulse is not so rapid, and has a fuller throb, which, with the other symptoms of torpor, are to be ascribed to the near destruction of life by the extensive destruction of parts, together with the effects of exposure to smoke and flame.

In treating these two species of burns constitutionally, wherever the injury was a more or less extensive scalding, without including nearly the whole of the body, I never hesitated to bleed to an extent proportioned to the injury and the symptoms produced, which, together with a large dose of laudanum, and the application of the resinous ointment, gave instant relief from all the symptoms, and the patient steadily recovered, without any sloughing or ulceration; but where the immersion of the body was complete, and of some continuance, of which I have seen two or three instances occurring in sea-water, they proved fatal in a very few hours. These cases happened before I employed my present practice; it is, however, very probable that they would have had the same termination, both from their extent and the difficulty of procuring the necessary applications. I had no hesitation in using the lancet freely in the cases of scalding, because it was evident no real debility could exist, and such a means was also affording the only chance of removing the excitement, and relieving the oppressed breathing, whether this was owing, either to the action of the heart not being able to overcome the accumulation of blood in the chest from the spasm, or want of regular action in the vessels of the surface—a direct want of action in the heart itself, or even an extravasation of fluid in the chest. In the cases of extensive burns from flaming bodies, I have never used the lancet or opiates, because there was no excitement to subdue, but trusted to leeches and other local applications, with laxatives, to relieve the stupor and coma, and to the means for supporting the strength of the general habit, looking forward to an extensive suppuration.

I have now brought to a conclusion the observations which at present I think necessary, in order to recommend the treatment proposed for burns; but before closing this letter, perhaps it may not be considered out of place to observe, that in consequence of the very frequent loss of life which occurs from the fires

in London, it has appeared to me, that by having a very stout blanket, at least twelve feet square, held upon the stretch by ten or twelve stout men, immediately under the windows or other places whence the individuals may escape, they would not hesitate to take this chance of saving their limbs and lives.

I am, sir,
Your most obedient,
THOMAS BROWN.

Mussleburgh, July 25, 1833.

REPLY TO THREE QUERIES RESPECTING CHOLERA.

To the Editor of the Medical Gazette.

SIR,

PERMIT me to make the following observations in answer to the queries proposed in a late number of your Gazette*, regarding the symptoms and treatment of Asiatic cholera.

First. In the course of a pretty extensive practice during the year 1832, principally in the counties of Ross, Midlothian, and Dumfries, I *invariably* remarked the movements after death alluded to by your correspondent. These movements were not, however, confined to the limbs, but were frequently observed in the muscles of the back and abdomen, especially the former. They commenced generally about a quarter of an hour after death, and continued from ten to thirty minutes, being always more violent, and of longer duration, in those cases in which the fatal termination had occurred during collapse than in any other. In such instances the body, from being of an icy coldness, became about a quarter of an hour after death considerably warmer, and the temperature continued to rise for some time. It was during this period that those movements were observed.

Secondly. I have never seen "oily dejections" in any stage of the disease.

Thirdly. Mercury, if administered during collapse, produced no visible effect, in whatever dose it might be prescribed; but if given at the commencement of re-action, it both hastened the effects of other remedies, and acted directly, by increasing, or rather restoring, all the secretions.

The period which elapsed between its exhibition and the manifestation of its effects, generally varied from twelve to sixty hours.

The dose (if administered in the form of calomel) should vary from ten to thirty grains, to be repeated (at such intervals as the circumstances of the case may dictate) till the requisite effect is produced.

This effect is the restoration of the paralysed organic functions of absorption and secretion.

I have the honour to remain, sir,
Your obedient servant,
T. ROSS JAMESON, M.D.

Bateman's Buildings, Soho-Square,
27th July, 1833.

DEFENCE OF EDINBURGH GRADUATES AS CANDIDATES FOR GENERAL PRACTICE.

To the Editor of the Medical Gazette.

SIR,

IN a communication signed, "Conservator," certain statements are made respecting the number of Scotch graduates that have been rejected by the Society of Apothecaries, which, although startling, are most probably correct,—as from the serious manner in which the *conscienciousness*, and so forth, of the apothecaries is descanted upon, Conservator seems to have special acquaintance with the worthy gentlemen of that body. A medical man, like myself, who has received his education at Edinburgh, and been examined by the tribunals there, cannot very comfortably swallow a statement in which one-third of the Scottish graduates are declared to be unfit to practise their profession; or, as Conservator states it, to "practise as apothecaries," which (by-the-by) may probably mean something else.

Supposing the statement true, it undoubtedly leads to inferences as to the mode and spirit examinations are conducted in at Apothecaries' Hall, which support those rumours of unfairness which is said to be evinced by the apothecaries towards Scotch diplomatists. Is it possible that men of such uprightness as Conservator states them to be, are more anxious to puzzle such individuals than to ascertain the amount of their knowledge? These graduates that are

* See p. 512, *ante*.

admitted on trial must be those purposely educated in England for apothecaries, by serving a five years' apprenticeship, and by studying two sessions at Edinburgh or elsewhere, might have taken out the apothecaries' certificate; but by studying four sessions, and taking the degree of M.D. it appears, by Conservator's shewing, they are still more unfit to practise as apothecaries, as in the latter case one in three are rejected, while in the former only one in seven. Inference the first that flows from this (and note it, Dr. Hawkins, for the next edition of your Elements of Medical Statistics) is, that the shorter the student's academic study, the more likely to pass the apothecary examiners; and inference the second is, that Dr. John Thomson, Christison, Alison, and Monro, of Edinburgh, and Drs. Thomas Thomson, Jeffray, Burns, and Badham, of Glasgow, must be men of small perceptions, utterly unqualified to act as examiners, or, at least, less so than the worshipful examiners of the Hall.

With regard to examinations at Edinburgh, (and of the other universities I know nothing) I would merely remark that Conservator, and his friends, the Apothecary Examiners, know nothing about them, and that they are such as few of those gentlemen, from their education, would be enabled to pass through. No individual can get over his examinations there in the easy manner Conservator insinuates; at least they could not do so fifteen years ago, and I know not that there are greater facilities now. It is quite impossible for a careless or uninformed student to procure a degree, as the candidate undergoes several examinations, both private and public. The insinuations of Conservator as to the inferiority of those graduates who choose to practise as general practitioners, are conceived in a bad spirit, and evince a rancorous soreness somewhere. A graduate of 23 or 25 years of age, acts wisely in practising generally for ten or twelve years, and will be an experienced physician at 35 or 40. No doubt the Apothecaries' Society do not like such individuals to do so; indeed, it is their interest to reject graduates, as it may prevent men who have received a first-rate medical education from opposing the apothecary examiners in general practice.

 "L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.
 —

The Physiology of the Organ of Hearing, deduced from its Anatomy as it exists in Man, and from Comparative Anatomy; together with its Pathology, and the Treatment of the Injuries and Diseases to which it is liable.
 By CHARLES CASWALL, Member of the Royal College of Surgeons, &c.

IN this new contribution to the physiology and pathology of one of the most precious of our organs, the author proceeds after a simple and clear method. He gives in the first place a description of the human ear, as it is in the adult; after which he gives an account of the same organ as it is found in brutes; with a comparative view of the differences in each genus. The physiology of the ear then engages the author; and, referring to the facts deduced from comparative anatomy, he points out why, in some of the inferior classes of animals, that part is so peculiarly endowed both in structure and function. In the pathological division of his subject he notices the effects of malformation, accident, or disease; and in conclusion, he attempts to shew what measure of relief can be afforded in such cases, and the remedies to be employed for such a purpose.

As a specimen of the author's mode of treating some of the more interesting questions which he takes up, we shall extract his remarks on the *functions of the tympanum*.

"The membrana tympani exists in all warm-blooded animals. All that want the tympanum have no membrane, and in some reptiles that have a tympanum the membrane is wanting. As it has been found to exist in man and the mammalia, so has it been described; and its use will form the subject for examination. Separately, distinct from the tympanum, what has been the use generally assigned it? I cannot state (after much investigation) that, independently of the cavity of which it forms a part, any definite organic use can be assigned to it. In 1799 Sir Everard Home delivered a lecture on this subject to the Royal Society of London, which was published in the Philosophical

Transactions of that Society for the year 1800. From these observations, somewhat like the following conclusions were deduced:—That as he (Sir Everard) had decidedly and distinctly demonstrated the existence of muscular fibres in the membrana tympani, so did he conceive the membrane to have the power in itself, independently of other parts, of modulating sounds for the acceptance of the auditory nerve; in the same manner as the iris is expanded or contracted for the admission of a greater or lesser number of rays of light, according to their strength or weakness.

“ Sir Astley Cooper, however, in a letter to Sir Everard Home (which is published in the same volume of the Philosophical Transactions as Sir Everard’s lecture), objects to the conclusions which the latter had founded on his observations; and two instances are adduced by Sir A. Cooper, proving that Sir Everard’s conclusions were fallacious: for in the first of these two cases, the membrane of one ear was destroyed completely, and only a fragment remained of it in the other; yet after the lapse of a very short time, great motion of the auricle became exerted, and the young gentleman (a pupil of Sir Astley’s), from whose case these statements were made, could hear with as much ease, and quite as well, as when the membranes were entire. I infer from Sir Astley Cooper’s remarks, recorded in the letter just alluded to, that when the membrane and only a part of the ossicula are destroyed, a diminution only of the power of the organ takes place; whereas if the stapes is also removed from the fenestra ovalis, perfect and complete deafness generally ensues. The observations of both parties are most interesting. I may pronounce, then, that an organic use, independently of other parts, ought not to be ascribed to the membrana tympani; and in its isolated and unconnected state, the only use I can imagine it to claim is, that of preventing foreign bodies gaining access to the cavity.”

In a subsequent page the subject is resumed, where, in treating of the voice, the author asks:—

“ If the tympanum is destroyed, can articulate sounds, or vocal modulations, be distinguished? No; unless an acoustic apparatus be employed, and then but inaccurately. When a part of the tympanum is destroyed—what hap-

pens? According to Sir Astley Cooper’s observations, which I have stated (or rather conclusions drawn from his statements, and which I consider to be correct), the auricle in some instances becomes conformed to an unusual province, and remedies in some measure the sustained loss. But are any other sounds heard when the tympanum is wanting? Yes, undoubtedly; and fishes, which have no tympanum, are well known to be capable of hearing sounds: they are attracted near to the spot whence music arises in such numbers, that in some parts of the globe it is used as a charm to entrap and take them. Perhaps it will be said that the tympanum is essential for hearing other sounds than those which proceed from the voice, particularly those that are soft and delicate; and musical sounds may be instanced. We must remember that all musical notes are brought to hear as nearly as possible to those of the human vocal instrument; and the greatest perfection to which it has been desired that musical instruments should attain is, the resemblance of notes issued from the human vocal organ. Sounds, therefore, *resembling* those produced by the voice of the human being, can as readily be received by the human tympanum, as if proceeding from the vocal organ itself.”

The argument is then fully illustrated by facts respecting the structure of the tympanum in animals; and we find the author, finally, discussing the opinion of Sir Everard Home touching the function of the organ, in the following terms:—

“ Sir Everard Home appears to me to have given to the membrana tympani a capacity with which, in the first place, it has nothing at all to do; and again, supposing its importance to be great, it is not so great as he believes it to be. These, however, are only my opinions; but I offer them as freely as Sir Everard appears to have offered his, at the same time with all due deference and respect to those he has advanced. In the 278th page of the third volume of his Lectures on Comparative Anatomy, published in the year 1828, the following observations are recorded:—‘ The cochlea has been considered by physiologists as one of the most intricate and curious parts of the ear, and on that account had a most important office assigned to it. This is now, however, to

be transferred to the membrana tympani; and upon attentive consideration of the subject, it will appear impossible for the cochlea to be of any use in modulating sound, since the ear is only intended to convey impressions received from external bodies; hence no impression can be communicated to the cochlea which has not been transmitted by the membrana tympani."

"It is evident, from the foregoing quotation, that something more than the modulation of the power or force of sound, is alluded to; and that the capacity, or office, with which I conceive the membrana tympani has nothing at all to do, is in the modulation of sounds; nor do I believe the cochlea to have any part in such a capacity; neither, in fact, has any other portion of the organ such a province allotted to it. Sounds are not modulated in any part of the organ. We will, just for the sake of comment, divide the five octaves of the voice into two parts, each possessing two octaves and a half; one part is an acute, the other part a grave scale. Now it is necessary for the acceptance of the lowest degree in the grave scale (reasoning from analogy), that the membrana tympani should be concave externally and convex internally, the membrane remaining, *comparatively*, in a relaxed state. But as the notes approach towards the acute scale, the muscles graduate the tension of the membrane; and again, as they approach still nearer, and pass, as it were, the median line, the muscle of the membrane itself becomes more and more active; and at the extreme point of the acute scale the membrane is made perfectly tense. Now these notes emanate from the voice, as they do from any other stringed instrument, in acute and grave sounds; they are not made acute and grave by the ear; the tympanum is regulated by the notes, and not the notes by the tympanum. The membrane is brought to an adaptation for the reception of the notes; first, by the muscles of the ossicula; and secondly, as the notes advance to the extreme point of the acute scale, the muscle of the membrane becomes more and more exerted. How then does the membrane modulate sound? The pleasures resulting from sounds of concordant notes are produced by the sensorium: delight is not experienced in the ear; the ear transmits discordant notes as well as those that are perfect, and

the sensorium perceives it;—how then can the membrana tympani modulate sound? It is not because the membrana tympani is unaccustomed to perfect harmony, that discordant notes are perceived by the sensorium, but the contrary; for as the sensorium from constant practice becomes more and more acquainted with the variety of sound and tone, so (as its perfection advances) are discordant notes more easily detected. Hence, then, the sounds are not modulated by the membrane of the tympanum; they proceed from the instrument that produces them to the sensorium; and, according to their tone, are certain parts called into action, as their conductor thither. Why should Paganini's performance on the violin be so superior in producing perfect harmony, if the membrana tympani modulated sounds? Why could not I, who am incapable of producing scarcely a note, produce the same delightful sensations as Paganini, if the membrane of the tympanum could modulate sound? It does not do so; and if more be required to explain that it does not, the case recorded by Sir Astley Cooper, before alluded to (and many similar could be advanced), is sufficient."

The pathological portion of the work is concise; and that relating to the treatment of the injuries and diseases of the ear is, we think, as brief as it is judicious. In his practical observations we could certainly have wished the author to be more copious, did we not fully agree with him in the hopelessness of benefit to be derived from routine practice in treating so intricate, mysterious, and very delicate an organ. Give a watchmaker a watch to repair, but tell him that he must not take the machinery to pieces, nor have more than a superficial glance at its outward construction, and see what answer he will make.

A Manual of Experiments illustrative of Chemical Science, systematically arranged. By JOHN MURRAY, F.S.A. &c. &c.

THE fact of the present being the third edition of this little manual, is a strong testimony in its favour; in addition to which, we can testify, from an examination of its contents, that both for matter and arrangement, it is a highly recommendable treatise for junior students.

and young people in general. It contains a great variety of useful and practical information for the successful pursuit of chemical study. That the author has had in view its adaptation to the purposes of a school-book, we infer from its being dedicated to Dr. Butler, of Shrewsbury.

Observations on the Illusions of the Insane, and on the Medico-legal Question of their Confinement. Translated from the French of M. ESQUIROL, by WILLIAM LIDDELL, M.R.C.S.

WE gave some interesting extracts lately from the observations of M. Esquirol, of which the small volume before us is a full translation. Mr. Liddell has executed his task carefully and cleverly; and we observe that he has added a number of notes illustrative of the original, and suiting it more immediately to the use of English practitioners.

MEDICAL GAZETTE.

Saturday, August 3, 1833.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

UNIVERSITIES, OLD AND NEW— MEDICAL DEGREES.

THE project of confiding to a reformed College of Physicians the power of conferring medical degrees in London, is looked upon, we are glad to perceive, with approbation by all those whose approbation is at all worth possessing. But like most other feasible, though novel projects, it has to go through its several ordeals, and to be scrutinized and censured by many who have strong prejudices against the slightest innovation, and who are particularly hostile to any change in the privileges and practices of our old establishments. It is asked by some, how it can be reconciled, that the power of giving degrees should be vested elsewhere than in a university?

Now, in whatever observations we may feel called upon to make relative to this subject, we would have it clearly understood, that we are not, in the most remote degree, advocates for the curtailment of any of the due and lawful powers belonging to our ancient and venerable universities. In maintaining that there ought to be, in the metropolis of England, a body properly qualified for conferring the sanction requisite for entering on the honourable career of a physician, we, in the first instance, look to the wants of the community, and we presently find that the mode suggested for supplying those wants, would also be eminently conducive to the better ordering of the profession. We argue that it is fitting to have established here a governing body, which, we are convinced, could more reasonably than either Oxford or Cambridge, in their present condition, confer on those whom it would judge deserving, and of whose merits it would have ample opportunity to judge—that sanction which for all ordinary purposes, should be fully tantamount to a university degree. This by no means precludes the fair competition of the old establishments—should they deign to compete; nor is there any thing in it to prevent such a reform in the existing sources of professional sanction as would render them even formidable rivals to a medical university in London. Those bodies might clearly so model their method of ascertaining the qualifications of medical candidates, putting it on a liberal, a practical, and a satisfactory footing, as should render a special establishment here almost wholly unnecessary. But seeing, as we do, that there is not the slightest chance at present of any such salutary change, nor any the most remote prospect of it—judging from past transactions and the tenor of habitual policy—we feel ourselves strongly called upon to advocate some new arrange-

ment, at whatever expense of prejudice, rivalry, or competition.

But with regard to the question—how we can think of reconciling the granting of degrees elsewhere than in one of the old seats of learning?—it is readily answered. We have already alluded to the power possessed by the Archbishop of Canterbury, of conferring degrees, both in arts and medicine, and we believe also in divinity; which at least shews that there is nothing in the locality of the Cam and Isis peculiarly essential for the purpose. It shews more. If the Primate be fitly endowed with such a power—a power by no means suffered to become a dead letter, even where a degree is to be conferred in a faculty foreign to his own—how much more suitably should such a body as a well-regulated College of Physicians be invested with such a privilege; especially when it should extend no further than the conferring of degrees in *medicine*? There is, however, another point to which we would allude, as we think it affords us sufficient grounds for the perfect reconciliation of an apparent difficulty. Let us look to the arrangements of the legal profession. How are the graduate practitioners at the bar admitted?—and is there nothing in the excellent order observable in the faculty of law that is applicable to the faculty of physic?

Perfectly analogous to the projected medical establishment which we advocate, there is in London a great Law University, which was instituted at a very distant period. It is made up of the four Inns of Court, corresponding to so many colleges, whence the students are called and admitted to their several degrees: they are admitted, in the first instance, to the degree of Barrister, answering to that of Bachelor, and ultimately, if found deserving of the honour, they attain the “state and degree” of Serjeant; which corresponds,

in every respect, with that of Doctor*. It is curious, also, that the circumstances out of which this arrangement sprung, as nearly as possible resembled those which at the present time make a similar arrangement necessary with respect to medicine. It was found expedient for those who professed the law of the land, to incorporate themselves into an independent institution, capable of originating and sanctioning a supply of practitioners for the public service. There was no alternative. The Common Law was *excluded* from the universities, as trivial and unsuited to the dignity of learning, the Canon and Civil Law alone being retained; in other words, that which was practical, and “came home to men’s business and bosoms,” was rejected, while that which was encumbered with the dust of antiquity and almost perfectly useless, through the weight of ecclesiastical lore, was held fast with an eagerness almost unaccountable. We submit that there is the strongest analogy between the two cases. The mode in which the old universities are even now affected towards medicine, (we mean medicine considered as a practical science,) is exactly the same as that which they displayed, centuries ago, to law considered in the same point of view. They do not teach (at all in one, or efficiently in either) medicine, such as would be suited to the wants of the community, or so as to keep pace with the advancement of science; and it is for this simple reason that we hold a new institution to be imperatively required for medicine—such as has been long since established for law.

Nor does the analogy terminate in the originating causes: it may properly be carried even into the working of each system? What is the form of proceeding adopted in the legal arrangement? A man becomes a barrister—that is to

* See Fortescue (Mr. Amos’s Edition), p. 192; Coke, 3 Rep. pref. and Blackstone, 1, 24.

say, a graduate in law — by being duly admitted from one of the Inns of Court. He is thus properly sanctioned for entrance on his professional career, by a body immediately competent to take cognizance of his qualifications; while all the time the powers of the universities are undisturbed: Oxford and Cambridge still continue to confer their degrees in law, and those degrees have their due value attached to them, and are indispensable for the attainment of certain privileges connected with legal practice. The doctor of laws, as is known, can practice in certain courts where the ordinary barrister or the serjeant at law cannot. And so might it undoubtedly be with regard to honours conferred by the old universities: the “M.D. Cantab.” and the “M.D. Oxon.” might still, and no doubt would, secure certain immunities, not accessible to the plain “M.D. of London.”

In one point only—but that one, perhaps, of some importance—do we fear that the parallel may not hold good. The titles adopted by the juridical university, however synonymous, are not identical with those in use at the ancient seats; and probably some people may reasonably suppose, that however the power of granting medical degrees in London might be conceded by the old universities, they would never consent to allowing them to be called by the same name. We are unwilling to anticipate causes of dissension, but we greatly fear that in this part of the arrangement, a very positive answer will be given to the question—“What’s in a name?”—for nothing short of the full and fair title, sanctioned by popular use, and uncurtailed in its fair proportions, will or ought to satisfy the legitimate claimants of medical honours.

THE MEETING AT BRISTOL.

We have perused, with much pleasure, the opening address of Dr. Carrick at

the Bristol meeting, and deem it but justice to say, that it is marked throughout with a temperate and wise tone, very much at variance with that outrageous spirit recommended by a contemporary. A few passages from the speech (we regret that we have not room for the whole of it) will give a fair specimen of the mode in which the all-engrossing subject of medical reform is handled by Dr. Carrick.

In reply to those who would fain make a party business of the objects of the Association, he says:—“We are in opposition to no man, or body of men, whatever. We associate for the legitimate object of our own gratification, our own instruction, and the advancement of medical science in its enlarged acceptance; and thereby, we trust, for the benefit ultimately of our fellow creatures. For myself I am free to avow, that to have an opportunity of meeting such a numerous and respectable assemblage of my medical brethren as I now see before me, many from remote parts, and some from a distance of 150 miles, is to me an ample recompence, were nothing more to arise from it. From my first entrance into professional life, it has ever seemed to me to be a most desirable and important object, to cultivate the friendship and society of my fellow labourers, to bring them frequently together, and to render them familiar with one another; and I can truly declare, that the happiest hours I have ever spent have been in the company of medical men. But besides the mere social enjoyment of such friendly intercourse, there are numberless advantages which arise from medical men associating with each other, and living together on gentlemanly and friendly terms. . . . Besides the opportunity it affords of a ready and easy means of collecting, preserving, and presenting to the medical public many valuable cases, and histories, and essays of great interest, which would otherwise be lost to the world, I cannot but look forward with I trust a well-grounded hope, that this society may in time prove eminently instrumental in improving the condition and structure of the medical profession; the just and proper organization of which, although hitherto grossly neglected by the Legislature, is vitally important to the best interests of the state, and of each individual person. It was well observed by the respected parent of this Association, in his excellent address already alluded to, that ‘the organization of the profession as it obtains, is not what it ought to be; for the whole system of medical polity in this

country is both defective and erroneous. Opinions differ widely as to the evils and the remedies; but few are found to commend the existing state of things. This subject is closely connected with the advancement of science; for if the profession were constituted as it ought to be, and as reason and sound principles dictate, the harmony that would be thus established among the several departments, could not fail to prove a direct means of their co-operating more cordially and efficiently in extending the science and improving the practice.' . . . We live in reforming days; but I am not a radical reformer—I would not rashly innovate for the mere love of change, neither would I decline reformation where palpable defects or abuses demonstrably exist. When, however, I consider the many obstacles which still stand in the way of wholesome and rational medical reform, and the various opposing interests, individual and corporate, which must be conciliated or overcome, I despair of living to see the day. Many of you will, I doubt not, have that satisfaction, and enter into that promised land, of which I can at best have but a Pisgah prospect. For my own part I can scarcely be considered as interested in the result, be it what it may; my race is nearly run. Yet, although I can neither derive any sensible benefit nor injury from what may happen, I cannot but feel warmly interested for the honour and advancement of that profession in which I have been actively engaged for more than half a century. In the meantime, gentlemen, it behoves us, as members of this Society, to do our best to eschew and turn aside the evil of an imperfect and ill-digested system. Your influence, well and temperately directed, may not be small in accelerating the necessary improvements in education and practice, as well as in extending the limits of medical science, and in diffusing its benefits to society at large—the object which must always be uppermost in all our aspirations and exertions. By acting with unanimity and kindly feeling towards one another, and with uprightness, humanity, and manly independence to the world at large, we shall best succeed in procuring for ourselves that protection and encouragement for our useful services, which the Legislature is either too fully occupied otherwise, or too indifferent about the matter, to attend to; and which the corporate bodies are, perhaps, too much interested in withholding. Gentlemen, I beg to apologize for having engrossed so large a portion of your valuable time, and to thank you for your indulgent attention."

COMMISSION DE LUNATICO.

—
In Lord Kingston's case, which was investigated last week at Brislington, the medical evidence was very clear and conclusive. The following extracts, we think, are worth preserving:—

Dr. O'Neill, of Mitchelstown, in Ireland, had known his Lordship for seventeen or eighteen years. Witness was physician to his Lordship's family; had frequently attended Lord Kingston for bilious attacks and severe erysipelas. On the 9th of April, 1830, was called in to attend him for lunacy, when he appeared to be labouring under great nervous excitement—his looks, manner, and motions denoting considerable mental aberration. He evinced much alarm, stating that persons were in the house who were about to deprive him of his property and life. Since the date just mentioned, his Lordship has never been able to attend to his own affairs, though there were occasional remissions of his disorder. Witness is of opinion that his Lordship's mental disease arose from bodily infirmities.

Dr. C. J. Fox, of Brislington, visited the Earl in conjunction with his father and Dr. F. K. Fox, usually three times a week since July 1830. Considered him all along labouring under delusions and erroneous ideas. He, however, displayed sound judgment on some points—for example, he could give an opinion of the value of cattle. In September 1831 his Lordship had had an attack of paralysis, followed by impaired memory, affection of the speech and bodily powers, and a state of dementia. In October same year had a second attack, followed by increased impairment of the faculties.

Dr. F. K. Fox deposed to the excited state of the Earl's mind on his first arrival at his father's asylum. His mind improved to some extent for the first year, although there was nothing like a lucid interval in it. The paralytic strokes reduced him to imbecility.

Dr. Pritchard stated, that he had just paid a visit to his Lordship, and found him unoccupied. Witness wrote some figures on paper, 3 and 3, and asked his Lordship what they made added together? He could not tell, nor could he read his own name. The effects of paralysis and epilepsy are much alike; the same as are witnessed in extreme old age, when there is no existing disease. A German writer divides this kind of imbecility into five stages, the last of which is, when the individual becomes inattentive to the common calls of nature. His Lordship's present

state is a want of comprehension, and an incapacity for any train of reasoning; he is in such a state as to be entirely incompetent for the management of his affairs. Paralysis deteriorates insanity; it will itself bring on that stage, and render a patient in a worse state. Both affect the same organ, the brain. He considered his Lordship to be in the last but one of the five stages.

The jury after a short deliberation found, "that George, Earl of Kingston, has been of unsound mind, without any lucid interval, since the 9th of April 1830 up to the present time, and consequently that he is incompetent to the management of his affairs."

HOTEL DIEU, PARIS.

CLINIQUE OF M. DUPUYTREN.

Case of Caries of the Scapulo-humeral Articulation—Amputation at the Joint—Complications—Death—Autopsy.

AMPUTATION of the arm at the shoulder-joint, said M. Dupuytren, appears to me to be indispensable, when the head of the humerus is bruised in consequence of a blow or a fall, and has become tumefied and enlarged to such a bulk, and with such changes in the neighbouring parts, as render it hopeless to expect a cure, or even a means of arresting the progress of the disease. It often happens that we have reason to hope the scapula and adjacent bones are sound, even while the humerus is seriously affected; and there is also reason to expect success from the same mode of proceeding when other parts of the body—the knee, the forearm, &c. are involved in a similar disorder.

Yet we should by no means be understood to advise the extirpation of the arm indifferently in all stages of the complaint. There is a period when the engorgement of the neighbouring parts, the suppuration which has set in, and the debility of the subject, render the operation wholly inexpedient. Yet it is highly practicable and proper at an earlier period: it is, in a word, the sole means of remedying a malady which to this day has put every other remedy at defiance.

Such were the reasons which induced me to operate on the patient, who lately lay at 26 in the Salle Ste. Marthe. If we have not been as successful as we hoped to be, it was because there were severe complications added to the primary affection,

which ultimately terminated in death. The patient in question was scarcely 30 years of age, he was of a lymphatic temperament, and came into the Hôtel Dieu in May last, complaining of six years of previous illness. The particular malady of which he complained, began with a sharp pain in the shoulder, attended with little redness; but there was some inflammation of the skin, and a thickening of the cellular tissue. The environs of the joint were painful to the touch, its posterior portion less so; the anterior and superior parts presented a tumor of about the size and shape of a large hen-egg. The application of the fingers to this tumor for the purpose of examining it, gave the patient much uneasiness. The forearm was unaffected in its movements, but rather turned towards the anterior portion of the trunk, and when the arm was brought in contact with the side of the body, it was not very tolerable to separate them again. Those were the signs from which the existence of an affection of the shoulder-joint was inferred.

To the methods which had been already tried out of the hospital, M. Dupuytren added the employment of a puncture through the anterior and most depending part of the arm down on the place where there seemed most fluctuation. By this the patient, now suffering under continued fever, appeared to be relieved. A considerable quantity of pus was drawn off, which had raised the deltoid, and seemed rather to come from the circumference of the articulation than from its interior. So much relief, indeed, was experienced by the patient, that he took advantage of it, to ask leave to go home to settle his affairs.

Upon returning to the hospital, after a fortnight's absence, he was suffering greatly: the pains were insupportable, the swelling considerable, and the fluctuation manifest. On the 28th May, M. Dupuytren practised an incision about the middle of the arm. A large quantity of pus, of a characteristically fetid description, issued forth, which came, no doubt, from the interior of the joint. From this moment the symptoms became more serious than ever, and in such quick succession, that amputation was evidently the *dernier resort*.

The great debility of the patient, however, not a little contra-indicated the operation. Was the chest sound? The patient said he never had felt any pain in that quarter, had never had cough; and he was most anxious to have the arm removed. M. Dupuytren was eventually obliged to have recourse to this uncertain method rather than leave the patient to certain death.

On the 5th of June the operation was performed. Commencing at the acromion, M. Dupuytren directed his first incision from above downwards, and from without inwards, to the side of the chest. A second incision, beginning at the same point, was brought down to the insertion of the great dorsal muscle on the humerus. Opening the capsule of the joint, the head of the bone was disengaged, and the muscles were divided which were attached posteriorly. All the vessels were tied. The articulation, as was expected, was found bathed in pus: union by the first intention was accordingly not attempted. Simple dressing was employed, and the patient brought back to his bed.

The appearance of the removed member fully justified the operation. The upper part of the humerus was profoundly carious; all the cartilages were destroyed, and the inflammation extended to the scapula.

On the 8th a change of dressing was required, in consequence of the copious and laudable suppuration which had occurred. There was no hæmorrhage or pain after the operation. On the 10th, still going on well; no shiverings; very little appearance of fever; the wound looking well; several of the ligatures fallen off; and on the 11th, so well was the patient, that M. Dupuytren would have closed up the wound altogether had it not been made for a caries, and had the scapula been quite untouched. But this favourable state did not last long.

On the 17th, at the morning visit, some accidents were observed connected with the urinary passages and the genital organs. The right testicle was engorged and painful. The urine (which had not been noticed till then) was charged with mucus and discharged with pain. The spermatic cord was hard, engorged, and painful even up to its entrance into the abdomen. It was clear that the patient had concealed some important facts co-existent, if not connected with his disorder. Upon being questioned about them, it was found that three years previously he had had a violent blenorrhagia, which was ill managed, and ever since which he had a running. In the patient's present condition, such a circumstance was of the gravest concern. An affection of the chest, with short and impeded respiration, cough, &c. now made its appearance. For the first ailment, leeches were applied, and an abscess was opened which was found to be formed all along the spermatic cord. But in the end, what with the abundant suppuration of the wound at the shoulder, the sweats, diarrhœa, cough, oppression, and the rapid progress of the tubercles which he had in the lungs, he sunk into a state of coma,

terminating in forty-eight hours with death.

The *postmortem* examination shewed the brain to be sound, but containing some little serosity in the ventricles. The upper part of the right lung was studded with tubercles, inflamed and suppurated. The left lung adhered to the pleura, and was also inflamed. A purulent abscess existed at the upper part of the right spermatic cord. The bladder, with its membranes, was considerably thickened. The mucous membrane had on it ulcerations like those commonly met with in the intestinal canal. There were also some greyish fungosities of the same membrane, and the bowels had similar ulcerations. The liver was sound.

As to the stump, it was going on perfectly well, and was almost completely cicatrised.

ST. BARTHOLOMEW'S HOSPITAL.

—

Operation for Stone on a Child—Cystitis(?).

CHARLES W. an extremely delicate boy, four years of age, was admitted into Darker ward, under the care of Mr. Earle, on the 18th of June, with symptoms of stone in the bladder. The urine, which was voided frequently, and with great pain, contained a large quantity of mucus, occasionally mixed with blood. On sounding him, a calculus was discovered; but from the extremely irritable state of the bladder, it was deemed advisable to defer the operation. The symptoms of stone had existed two years, but the child's health did not appear to have become impaired.

An alterative powder, consisting of Hyd. cum Cretâ, gr. iss. was ordered to be taken every night, and a drachm of castor oil in the morning.

20th.—No relief.

Mucilag. Acaciæ, ℥ij.; Decoct. Hordei, ℥xij.; Tr. Hyosciami, ℥xvj.; Pot. Nitratis, ℔ij. M. ft.

Sumat iij. cochlearea magna, ter quotidie.

28th.—The irritable state of the bladder still continues; the urine contains a large quantity of mucus, and is always more or less tinged with blood.

R Ext. Uvæ Ursi, gr. v.; Mucil. Acaciæ, Aquæ Distill. aa. f. ℥ij. Ter quotidie.

July 7th.—The urine has assumed a more healthy character, and the condition of the child appears more favourable for

the operation, which Mr. Earle therefore resolved on performing to-day. The child being placed on the operating table, the sound was introduced; but the stone could not be detected either by Mr. Earle or Mr. Vincent. The attempts made to find the stone produced great pain and irritation, and the bladder expelled the urine highly tinged with blood. Mr. Earle being satisfied as to the presence of the stone, proceeded to the operation. The stone was of very small size, and being placed just at the entrance of the urethra, some difficulty was experienced in seizing it with the forceps.

In the evening he was restless, and complained of pain in the lower part of the abdomen.

Hirudines iv. perineo. Fetus.

8th, 3 A.M.—Is crying with pain in the belly, but is irritable and peevish, and will not suffer the abdomen to be examined. His pulse is frequent and skin hot.

Hirudines, vj.; Hydrarg. Submur. gr. ij.; Pulv. Ipecacuan. Com. gr. ij. 3tis hor.

6 P.M.—Is still complaining with pain, but will not suffer the abdomen to be touched, although he bears the pressure of the bedclothes without complaint. The urine passes freely through the wound, and contains a large quantity of mucus.

Hirudines iv. abdom.

9th.—The symptoms are somewhat relieved, but there is still heat of skin, frequency in the pulse, and pain in region of the bladder. The urine is accompanied with a still larger quantity of mucus.

Hirudines iv. abdom.

10th.—Better.

16th.—He has been gradually improving, but is not yet in a satisfactory state.

On the same day, Mr. Earle operated for stone upon a man 42 years of age. The stone was composed of lithic acid, and was of large size. The operation was skilfully performed, and the patient has since gone on well.

PRIZE SUBJECT.

THREE prizes, severally of £50, £30, and £20, are offered for the best three essays on the following subject:—"On the present State of the Medical Science and Practice in the United Kingdom, and the most advisable and efficient mode of promoting the Advancement and the Improvement of both in all their branches." Dr. Epps, of Great Russell Street, is the referee as to the conditions and further particulars.

HONOURS TO HUFELAND.

THE fiftieth anniversary of the doctorate of this distinguished man was celebrated on the 24th ult. by all the learned bodies of Prussia. At Berlin, orations in honour of him were pronounced, and a grand public dinner was given. The King took that opportunity of creating him a knight of the Red Eagle of the first class. The Universities of Göttingen and Breslau, and the physicians of Warsaw, also did him homage. A valuable medal, struck for the occasion, bears the head of Hufeland and the following inscription:—

*Naturæ præcepta colens, morbisque medetur,
Filaque Parcarum lentius ire docet.*

The memorable day was spent by Hufeland at his country seat, near Berlin, surrounded by his family and intimate friends.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE STOMACH AND
BOWELS.

—
EPIDEMIC CHOLERA.

IN 1817 a disease appeared in India, in some particulars like English cholera—so far as there is a discharge upwards and downwards, severe pain in the abdomen, cramps of the extremities, and at length of the whole body, with great exhaustion.

Impropriety of terming it Cholera.—From its resemblance to the other disease in these particulars, it was unfortunately called *cholera morbus*; but there is this decided difference in the two affections—that whereas in what we understand by cholera, or did understand, the motions are all bilious; but in this, which broke out in India in 1817, the motions have no bile in them whatever, but are perfectly white and watery. On this account, if it were necessary to borrow a name from another disease to give to this, it would be better to call it *leucorrhœa* than cholera: the discharge being white, *leucorrhœa* certainly would have been a less objectionable name.

Symptoms.—In the disease which broke out in India, the first symptoms were languor, uneasiness at the stomach, nausea, and common diarrhœa; and then, all at once, about three or four o'clock in the morning, violent vomiting and purging occurred, but occasionally these took place without any premonitory symptoms. At

the same time, or very soon after, excessively severe spasms were felt in the extremities and in the abdominal muscles, so as not only to make the patient exclaim with agony, but sometimes to make it necessary to call in the aid of several persons to hold him. The countenance, in a short time, became ghastly; the skin shrivelled; the features contracted and elongated; the eyes a little suffused, slightly tinged with red, and sunk in the sockets; the lips purple, or of a black cast; the base of the eyelids likewise purple; the skin and the nails blue; the fingers not only shrunk but shrivelled, exactly like the hands of an old washerwoman. At the same time there was extreme thirst; a great sensation of heat in the throat; the temperature of the whole body was excessively cold; the tongue and the breath were likewise cold; sometimes the tongue was quite clean and of the colour of lead, but occasionally it was white, and had a tough, or (as it has been described) a leathery coat, and occasionally it was covered with sordes, but by no means always. The pulse, of course, became exceedingly weak and exceedingly quick, and at last it could not be felt at all in the wrists, though it might still be perceived at the heart. Extreme restlessness took place, so that the patient could scarcely bear the bed-clothes, and endeavoured to toss them off. The breathing, like the pulse, became more rapid than in health. It was found that, in the expirations, only one-third of the usual quantity of carbonic acid was given off. The blood that was taken was found to be thick—some say pitchy and uncoagulable. The venous and arterial blood were equally black, and in the worst cases the blood would not flow at all. It was likewise observed that no urine was discharged; deafness was noticed as a frequent symptom, and also tenesmus. Occasionally, however, there was scarcely any vomiting, but extreme debility—extreme loss of bulk, shrinking of the body, the corrugated state of the fingers, and the

violent spasms. These cases were considered to be worse than those in which vomiting and purging took place. This disease differs from our cholera in there being danger where there is scarcely any evacuations; the danger of the disease not depending upon, and being in proportion to, the loss of the substance of the body. Sometimes it is said that no spasm was felt, in addition to there being neither vomiting nor purging; and this was considered still worse. The patient was said to be struck with death; his pulse became imperceptible, and death very soon closed the scene.

Irregularity in the occurrence of the Symptoms.—There was great irregularity as to the occurrence of these things; patients sometimes vomited and were purged before they experienced spasms, and sometimes spasms occurred at the onset of the disease. Occasionally blueness of the nose and about the eye-lids was not observed, and sometimes there was no corrugation. There was by no means uniformity in the symptoms.

Symptoms immediately preceding Death.—Before death it was very usual to find the spasms, the vomiting, and the purging cease, and for the patient to lie perfectly still, with the loss of the vigour of his mind, but with a perfect preservation of his reason. He would be conscious of all around him, but wish not to be disturbed, and he would take no nourishment. He would remain tranquil, as if he were waiting for the moment of death.

The duration of the disease was sometimes only a couple of hours, and sometimes it would not destroy life for the greater part of a day.

When the patient was lying in that quiet state, waiting, as it were, patiently for his death, the pulse at the wrist would not only be still, but the action of the heart sometimes could not be felt; at least, so it was said. Whether the ear was employed to ascertain whether the heart acted or not, I do not know. I presume it is common enough, in different diseases, for the pulse not to be felt while the heart still continues to beat.

Before death, it was occasionally noticed that the temperature would return, and hopes of recovery were sometimes entertained; but these were for the most part unfounded: the patient presently sunk. It was likewise observed, that after this extreme exhaustion, the face would sometimes become flushed, the temporal arteries become distended and throb, the patient lie in a somewhat delirious or comatose state, much in the condition of a person in typhus fever. The voice was weak, and very peculiar.

Morbid Appearances.—After death, an im-

mense quantity of white turbid fluid, with flakes of a very white substance, were found in the stomach and in the intestines, while no fluid whatever was found in the urinary bladder, and that organ was contracted to the smallest possible size. These were general occurrences. It was usual for neither feces nor bile to be found in the alimentary canal, but the gall-bladder generally (not always) was found full, and sometimes it was remarkably distended; so that there was no want of bile, but none passed into the alimentary canal. The veins were usually found greatly distended with blood, so that the hepatic, intestinal, and mesenteric veins, were remarkably distended, but those of the spleen were not quite so full. Congestion also occurred continually in the lungs and in the head. Sometimes there was a rosiness of the external surface of the alimentary canal, and sometimes of the internal. There was usually, too, a great congestion of blood in the heart itself. The abdominal muscles were found, by Dr. Davy, to be flabby and red, but of course not inflamed. The urinary bladder, although containing no urine and being so greatly contracted, had generally a sort of whitish mucus with flakes upon the inner surface. After death, one very remarkable phenomena presented itself, which was that the temperature of the body was higher than during life; so that a very high degree of heat was found on plunging the hand into the body. Another very remarkable circumstance is mentioned—the occurrence of a twitching of the different muscles of the body after the person was completely dead: the fingers, the toes, and every part of the face, were seen to move. Observations of this description were made on two subjects—the one a Caffre, and the other a Malay. The former died twenty hours after the first seizure, the complaint baffling the most powerful remedies. In fifteen minutes after he expired the fingers of the left hand were observed to move, then the muscles of the inside of the same arm were contracted in a convulsive manner, and the like motions were slowly propagated upwards to the pectoral muscles. The muscles of the calves of the legs contracted in like manner, bundles of their fibres being drawn together in a tremulous knot. The muscles of the inside of the leg and thigh were forcibly contracted in a vermicular manner. The muscles of the face and lower jaw were similarly affected, and finally those of the right arm and right pectoral muscle. These motions increased in extent and activity for ten minutes, after which they gradually declined, and ceased twenty minutes after they began. In regard to the Malay, about fifteen minutes after he expired the toes

began to move in various directions, and the feet were made to approach each other. Muscular contractions were speedily propagated upwards, along the inside of the legs and thighs. The thighs were turned slowly inwards, so as to approach each other, and again outwards; the whole of the lower extremities moving on the heels, as on pivots. These motions proceeded upwards, producing a quivering in the muscles. In five minutes the upper extremities began to be similarly affected: the fingers were extended, and often rigidly bent inwards; pronation and supination of the hand were steadily, though slowly, performed. The same quiverings were observable as in the lower extremities, and extended to the pectoralis major muscles and the superior margin of the latissimus dorsi. The muscles of the face moved, and the head was observed to shake. The total duration of these appearances was half an hour. By moving or pricking the arms or limbs, these contractions were rendered stronger, and again renewed where they had ceased.

This is the account which has been given by various writers who witnessed the disease in India.

Description of the Disease as it prevailed in London.—I will now describe to you the disease which has lately prevailed in London.

Among the patients whom I have seen, there has been a great variety as to the mode of attack, and as to the order of the symptoms after the disease has begun.

Varieties in the Mode of Attack.—With regard to the first point—the mode of attack, some persons have been seized suddenly, others have had diarrhoea for some time previously. Those who were suddenly attacked were seized generally early in the morning, after going to bed perfectly well, and discharged by vomiting and purging a turbid whitish fluid, containing white flakes. There was violent pain in the abdomen, violent pain in the extremities, dreadful cramps in the fingers, toes, arms, and legs. In two or three hours from the moment of the attack, I have seen the eyes sunk in the sockets, blueness round the base of the eyes, blueness of the nails; in some cases blueness somewhere upon the extremities, and in one case blueness of the whole body; no discharge of urine; intense thirst; a great sensation of heat within; extreme restlessness; the tongue of a colour like lead; and in the case in which the body was blue all over, covered with a white and leathery crust; a very feeble pulse, and at last no pulse whatever in the extremities, although it could be felt at the heart. The pulse and the respiration were very rapid: I have counted the respiration 36 in a minute. There has

been a great fall of temperature—so that the hands, the tongue, and the breath (as it came from the body), were cold. On passing a thermometer into the mouth, I have found it as low as 84 deg.; ranging only, at any rate, between 80 and 90 deg. There has been a cold sweat on the extremities, and then at last the patient would remain free from all restlessness—free from pain, free from vomiting; and would lie perfectly still, conscious of every thing, but with a desire not to make the least exertion, apparently tranquil, and waiting for his dissolution. Then, before death, I have noticed the temperature rise—the coldness cease; and after death the temperature has risen still more. I may mention, that in the case where there was such great blueness, no sooner had the patient expired than the blueness was diminished. I did not observe whether it diminished before death, but I noticed it immediately afterwards; and in an hour there was nothing of the colour to be seen. There was a twitching of the muscles; so that one finger, after death, would be drawn in, and then another, and the lower jaw would move up and down, and you might see a quivering of the muscles inside the thighs. The voice was weak, and there was great peculiarity in it.

Morbid Appearances.—After death, the stomach and intestines were usually found filled with white fluid, containing white flakes. There were various appearances both internally and externally of the alimentary canal; sometimes it was rose, and sometimes pale. The urinary bladder was empty and exceedingly contracted. The congestion in the venous system was very great. The mesenteric veins were full, and the venæ cavæ appeared distended to the utmost: they looked like a bell rope in a drawing-room. The heart was observed to be full, and the blood both in the ventricles and auricles was grumous—half coagulated. There was congestion sometimes in the head, and sometimes in the lungs.

Identity of the disease in India and in London.—Now no one possessed of common sense can doubt for a moment that the disease which occurred in India, and that which we have seen here, are precisely the same.

A new disease.—I should think no one can doubt that it is different from the disease commonly called *cholera*, which is marked by a discharge of bile, and in which the danger is in proportion to the extent of the evacuations. It cannot be said that this disease is only a severe form of common cholera, because the mildest cases are not at all like common cholera—they are not characterized by a discharge of bile. If it were cholera, only severe, the mild

cases ought to be equal to the very severe ones of the common cholera of this country; but instead of that, they are all characterized by an absence of bile, and by these peculiar dejections.

Again, it has been said that this disease is not only essentially common cholera, but that it is a disease we have all seen. I raise my voice in saying that it is a disease which I never saw before, and I think that if it had previously occurred in London, from being connected with a large institution, I should have seen it; but I certainly never saw any affection that bore the least analogy to it. It would not be more absurd to say that measles and common bronchitis are the same, because in both there are certain morbid appearances of the air-passages, than it is to say, because there is vomiting and purging in this disease as well as in common cholera, they are the same. A variety of diseases of the skin, which are distinct from each other, have an appearance in common, and measles, scarlet fever, and other affections, were formerly all jumbled together—no diagnosis was made between them, simply because there was redness of skin.

If you look at Celsus and Sydenham, you will find that the cholera which they describe is very different from this affection. Sydenham says it prevails at the end of summer and during the autumn, as regularly as vegetation comes in spring; whereas, this disease occurs at all seasons, and has no connexion whatever with heat. Sydenham describes it as a discharge of bile, and not of the peculiar fluid which we see in this affection. I cannot but believe that it is totally distinct from common cholera, and that it is a disease never seen before in England. I have conversed with practitioners older than myself—with men of the greatest experience—and they declare that they have never met with such a disease before.

History.—I may now detail some few particulars respecting the disease. It was thought in India that the natives suffered from it more than the Europeans. Thousands of natives perished near Bombay, while of the Europeans, who had good food and good clothing, six only were affected. It was found to attack those who had the worst diet, who were the worst clothed, and were worst off in all respects. It was found to prevail at all temperatures and all seasons—in healthy and in unhealthy situations; both in dry and in moist places. It prevailed in spite of the monsoons, and not only in every direction of the wind, but in all hydrometric states of the atmosphere. There was great doubt whether it was contagious or not. Some thought it proceeded where there was no communication, just as well as when there

was. It was found suddenly to stop without any apparent reason, and then to go on again; pass from one district to another, as regularly as any other disease would, and then, as soon as it ceased in one place, it would begin in another. It was said that it broke out in the Mauritius, 3000 miles from a place where it had prevailed, but it was after a vessel had arrived from that spot. Certainly, if you read the accounts of the disease as it appeared in different countries, you find a mass of evidence tending to prove that it is contagious, and then you find a mass of doubtful circumstances which unsettle your mind again.

Now I need not say that it turned at last towards Europe, and proceeded pursuing a north-westerly direction, till at last it has reached this country, and with all the observations that can be made, it is still a matter of doubt whether it is contagious or not; but the particulars observed here and on the continent perfectly agree with what I have stated, namely, that the poor have been affected much more than the rich, and that those who are the worst fed, clothed, and lodged, have all suffered in the greatest degree. We have a striking example of this so far as the disease has hitherto proceeded in contrasting its ravages in London with those it has made in Paris. Here the greater part of the people are well fed, better fed than in any other part of the world: they eat more flesh, and that flesh is of such a quality as is scarcely to be found in any other country; besides which, they are better clothed and more comfortable, and instead of trashy wines, they have good sound ale and porter and malt liquor of all kinds; but in Paris the air is bad; the people have very little water, and the water for the purposes of consuming is very bad; the inhabitants are crowded together, I know not how many families in a house, with little ventilation; the streets are narrow, and together with this the houses are dirty; the population live on what we Englishmen consider trash, not roast beef and mutton, but all sorts of dishes made up of bread and vegetables, with a little meat boiled in water to colour it, or to give it a flavour; and drink not good beer, but thin wine: and we all know that this disease has committed infinitely more ravages, done infinitely more mischief there, than it has here. This completely accords with what was observed in India.

Question of Contagion.—In regard to contagion, we have in this country many observations which tend to shew that the disease is contagious, and then we have cases occurring where we cannot imagine communication could have taken place. You will see in the MEDICAL

GAZETTE (vol. x. 31) a reference to a work by Dr. Haslewood, in which several facts are mentioned which go to shew the contagiousness of the disease, and these, together with facts which I have noticed myself, have created a strong suspicion in my mind that it is contagious; but while I am inclined to believe that, yet I am satisfied that it will spread without contagion at all. It may spread independently of contagion; but if the disease do occur in an individual, I cannot but think that that individual may communicate it to another. Of course you will find a large number of exceptions to its spreading, where you might, *à priori*, expect that it would spread. The disease has great difficulty in attacking those who are in good health and well off, and in this respect it differs from syphilis, itch, and small pox, and therefore though thousands may be exposed to the contagion of the disease, if contagion exist, yet they will be almost sure to escape. This must be taken into consideration when you consider whether the disease is contagious or not. If a number of persons be exposed to it, and escape, yet this is nothing more than we should expect.

Fatality.—In regard to the fatality of the disease, it was observed in India that much good was done by medical treatment. It is said that at Bombay, where there were from 200,000 to 220,000 inhabitants, there were 15,945 cases: of these, 1294 took no medicine, and all died; but where medicine was employed, the deaths were reduced to six-sixths per cent. It was supposed there, at least it was stated so in books at the time, that by the administration of large doses of calomel and opium, occasional bleeding, and the hot bath, great good was effected, and that many lives were saved. Some persons gave calomel in small doses, and some gave scruples, with a drachm of laudanum, altering this according to circumstances. Others bled their patients, when they could get blood to come, and it was said that that treatment was also very successful. Some practitioners adopted both plans. Some recommended strongly the use of magnesia and other absorbents; indeed, one celebrated writer says, that magnesia and absorbent specifics have saved thousands of lives. Such was the treatment there, and the success was, as I have stated, considered to be very great.

Spirit-drinkers most liable to the disease.—I did not mention that it was well ascertained, that not only those who were badly off, and in bad health from some other disease, but those who are in the habit of drinking spirits, have in London been very liable to the disease. I do not know that

such an observation was made in India, but I presume that drunkards there suffered the same as here. In Europe, however, it is an undoubted fact, that that portion of the lower orders who had every thing calculated to make them in good health, but who indulged in spirit drinking, were sure to suffer; and this has been observed with regard to other diseases. However well persons may be off, yet if their body be enfeebled they are rendered increasingly liable to the disease.

Treatment.—In regard to the treatment in this country, I cannot but think that if all the patients had been left alone, the mortality would have been the same as it has been. I think that if all the persons attacked with cholera had been put into warm beds, made comfortable, and left alone, although many would have died who have been saved, yet I think altogether the mortality would not have been greater than after all that has been done; for we are not in the least more informed as to the proper remedies than we were when the first case of cholera occurred; we have not been instructed in the least by those who have had the disease to treat. Some say that they have cured the disease by bleeding, others by calomel, others by opium; and others again say that opium does harm. No doubt many poor creatures have died uncomfortably, who would have died tranquilly if nothing had been done to them. Some have been placed in hot water, hot air, and had opium and calomel, and other stimulants, which altogether has been more than their system would bear, and more than what would have been borne, if they had been so treated in perfect health.

I am sorry to say, that of the cases I have had to treat, the patients have nearly all died. I tried two or three sorts of treatment. Some had opium and calomel in large and full doses, but they died. Hot air was applied externally, and I got two to breathe hot air. I had a tube passed through boiling water, so that they might inhale hot air. It was found in vain to attempt to warm people by hot air applied externally; they were nearly as cold as before; you could not raise their temperature, and therefore I thought of making them breathe hot air; but both patients died about the period that death usually takes place.

It has been said that saline treatment was likely to be of use, and I accordingly tried it in some patients. At first I exhibited half a drachm of carbonate of soda every hour, and thinking that might not be quite enough, I exhibited a drachm; and in one patient at St. Thomas's Hospital I ordered an injection containing an

ounce of the same remedy; but the greater part of it came away, and the patient died. Hot air was used in this case as in the others.

Chemical qualities of the blood and dejections.—This leads me to speak of the chemical qualities of the blood, and of the discharge from the alimentary canal. It has been said that the contents of the latter were alkaline; but I have examined that point in several cases where no alkali had been taken, and so far from the observation being correct, I found them exceedingly acid. In the case of a man who was blue from head to foot, and who had twitches after death, the contents of the stomach were exceedingly acid, but were less and less so as we went downwards, till we got to the large intestines, and there they were natural. In the patient who took large doses of the carbonate of soda, and had an ounce thrown up, the contents of the stomach were then only neutral, while those of the intestines were acid; and then when we came to the rectum, where some of the carbonate of soda still remained, were they alkaline. The cases that I have examined have not been numerous, but in all of them the contents have been principally acid, and in no case were they alkaline except in the one I have just mentioned.

Dr. O'Shaughnessy has published some observations and experiments on this subject. He says, "the summary of my experiments may be described as denoting a great but variable deficiency of water in the blood, in four malignant cholera cases; a total absence of carbonate of soda in two; its occurrence in an almost infinitesimally small proportion in one; and a remarkable diminution of the other saline ingredients." It would appear from these four cases, that there is less serum in the blood, and therefore you see why it is thicker in this disease than in health; and there is also less saline ingredients in it. "Again," he says, "in the dejections passed by one of the patients whose blood was analysed, we find preponderance of alkali, and we recover the other saline matters deficient in the blood." Thus he supposes that the blood loses its saline particles, that they are discharged into the intestines, and that you find them there in the same proportion as the blood has lost them. But although that may be the case, it is not clear that the dejections are of an alkaline quality—that is to say, that there is an excess of alkali in them.

In regard to the treatment, I really can tell you nothing; but I know that patients feel intense heat within, and intense thirst, and find great comfort arise from cold drinks. I understand that in Vienna the custom was to allow ice, which the pa-

tients took with great avidity, and derived great comfort from it.

DISORDERS OF THE DIGESTIVE ORGANS.

The disease of which I shall now speak is commonly called indigestion; but I would rather speak of it under the denomination of disorder of the digestive organs at large, because indigestion applies to affections simply of the stomach, whereas this affection implicates the intestines as well as the stomach, and indeed all the organs concerned not only in chylification but in excretion.

Now *indigestion* is usually termed in medicine *dyspepsia*, and you will sometimes find it mentioned under the name of *apepsia*; the one meaning difficult digestion, the other no digestion at all, and the third slow digestion. However, these all mean precisely the same thing.

We are now, therefore, to consider that derangement of the digestive organs which is generally attended with indigestion, but many of the symptoms of which take place without indigestion. Many persons will digest very well, and yet when they have no food in the stomach they are filled with wind: but this ceases on food being taken.

Sympathetic Derangement.—If any organ in the body suffer severely, the stomach is very much disposed to sympathize with it. The stomach, the heart, and the head, are particularly affected when any material derangement occurs in the frame; the stomach more particularly, perhaps, than either of the others, and the intestines generally become more or less affected at the same time. You know that in all acute diseases, in all violent accidents, the stomach feels the shock; there is anorexia, loss of appetite, frequently nausea and vomiting, and either costiveness or purging. The forces generally become depraved in their quality, uneasiness is usually felt in the stomach or intestines, and there is perhaps even pain and tenderness. Very frequently the patient is rendered more uncomfortable from the sympathetic disturbance of the stomach and bowels than from the original affection itself. In chronic diseases (as, for instance, in diseases of the heart, liver, and lungs,) the stomach and intestines are most materially affected.

But besides these effects—mere sympathetic circumstances from the derangement of other organs—we have these parts deranged originally.

Symptoms.—I will now proceed to consider all the symptoms which characterize those affections which pass every day under the name of derangement of the digestive organs.

Anorexia.—In the first place, loss of appetite is a very common symptom; and this is called, in medical language, *anorexia*, from *a*, priv. and *orexis*. Sometimes, however, the appetite is not lost, it is only irregular; the patient being able to eat well one day, though he cannot eat another. Sometimes the anorexia amounts to loathing—the patient not only cannot eat, but the idea of it disgusts him.

Pica.—Sometimes the appetite is not deficient simply, but is depraved; which is particularly seen in females, and is called *pica*. You will sometimes see young ladies long for chalk, cinders, sand, and they will bite glass, munch it, and when it is small enough they will swallow some of it. I saw a lady the other day who ate brown paper—not hot-pressed and gilt-edged, but *brown* paper. She longed for something to eat, but did not know what; she wished for something that she had never ate before, but she could not tell what, nor could I. I have heard of cases where the patient longed for raw flesh, and even live flesh; so that some have eaten live kittens (this is an absolute fact) and rats. In the same way some have been known to long for the contents of snuff-boxes, and even for manure. One man's case is described who ate a live pig, leaving the intestines, but after a little while he ate them also. There is a case described at full length in a German work, of a boy who had such a longing for lime that he ate all the mortar he could pick out of the wall; and being well horsewhipped for it, he then commenced on a neighbour's wall: the neighbour, however, smeared it with a decoction of wormwood, in order to prevent him, and he could no longer relish it; but he then went to the kennel in the street and sucked up the sand. He had a desire for something dirty. After this he got to some quick lime, and was forced to drink a large quantity of water, to extinguish his thirst. The mucous membrane within had a distaste for what is called "good food," but in other respects he was quite well. I recollect having read of a girl, and also of a student at Leyden, who always ate spiders when they could get them, and no harm arose from it. I have read of a man who disliked bread, and never ate it; but he was seized with a quartan ague, and then ate a large quantity: he recovered from the ague, and the disgust towards bread returned again. You know that this disease occurs even in moral young women who do not menstruate well, as I mentioned when speaking of chlorosis; and many pregnant women have some strange longing of this description. Every one must have met with circumstances of women longing for what it was

difficult to get—longing for things out of season. There was one who longed for a bit of the priest's sleeve, and contrived to get at it and bite it; not caring for his excommunication. I could relate cases almost without end of this description. One dipped her bread in a tar-tub. I never met with these extreme cases, but every one must have read of instances of this nature.

Bulimia.—Sometimes, however, the appetite is excessive, so that people will eat an immense quantity, and this is called *bulimia*. You will recollect that I mentioned, when speaking of fever, that this has sometimes occurred as a temporary symptom of another disease. People will eat many pounds of meat and bread in the course of a day.

Nausea and Vomiting.—Besides these affections, the stomach sometimes experiences attacks of nausea and vomiting. Some vomit only the food they take, others vomit a viscid secretion; some vomit more or less constantly, and some vomit only in the morning—and in the latter case it usually arises from drinking. When the disease has become very severe, some will vomit on the slightest motion. Then again, you will frequently find people, labouring under this affection, complain of intense thirst, and their tongue is foul and covered with a yellow or a creamy mucus. Sometimes it is white, dry, and brown; but whatever appearance it has, it is worst in the morning. It is frequently red at the same time, either at the tip or the edges. Sometimes it is the papillæ only that are red; they appear separate, like granules of cayenne pepper. Sometimes the tongue is red all over, and then it may be moist or dry, glazed, or dry and cracked.

Fætid Breath.—There is frequently fætor of the breath. Sometimes the smell is sour, sometimes it gives you the idea of sour flesh, sometimes it is like cabbage-water, and occasionally it is absolutely fecal—so that it is impossible to stand near a patient who has what is commonly called a *smoky chimney*. I mentioned that the most horrid kind of fætid breath frequently arises from a depraved secretion within the tonsils. Of course you will have a diseased odour of the breath from other circumstances than any of these. It will arise from a diseased bone, and sometimes even from carious teeth. This is not so disagreeable to others, but it is very unpleasant to the patient himself, from there being a bad taste in his mouth. Sometimes the taste is bitter, and sometimes they say it is particularly offensive.

Eructations.—Eructations are very common in this affection, and these may be either simple or fætid. Those which are

inodorous are generally experienced when the stomach is empty, and probably arise from a secretion of air by the surface of the stomach; but those which are foetid arise, I presume, from the contents of the stomach undergoing a certain degree of fermentation, or sometimes from the patient being costive. It appears that a portion of the faecal odour, if not the faeces, is absorbed; for some persons who are exceedingly costive have very foetid eructations, which are removed by regulating their bowels. In some persons, it is only when certain articles are taken that the breath becomes offensive—something of sulphurated hydrogen is given off from the substances.

Watery Fluid.—It is very common for the mouth to become filled with watery fluid, and often very suddenly. Sometimes you will see the patient's mouth constantly open: I have seen patients spit a pint a day. Occasionally the fluid is tasteless, but more frequently it is salt, or sour, and occasionally it is very acrid indeed—it contains a large quantity of muriatic acid. I believe it is often felt to be very cold; patients complain of its coming up as if it proceeded immediately from a spring.

Vis id Mucus.—Independently of this fluid, there is frequently an excessive quantity of viscid mucus, chiefly hanging from the pharynx, and causing a constant desire on the part of the patient to hawk it up. Many cases of this description are mistaken for affections of the air-passages. I myself was for some time completely in the dark respecting it, conceiving that persons had a constant discharge from the air-passages when they had nothing more than indigestion.

Subst nces vomited.—The vomiting may be either simple food which has become exceedingly sour and acrid, or foetid, or it may be bile; so that you have every variety of vomiting, just as you have every variety in regard to the appetite, in regard to the appearance of the tongue, and in regard to the eructations.

Gastrodynia and Pyrosis.—To descend lower, there is tightness and fullness of the abdomen, chiefly at the epigastrium, and chiefly after meals: frequently there is an aching and sometimes excessive pain there. Occasionally this is experienced only after meals, and occasionally only when the stomach is empty. This pain, if it be unaccompanied with inflammation, passes under the name of gastrodynia; and if with this there is a flow of fluid into the mouth, the two circumstances together are called *pyrosis*.

The pain is sometimes sudden, comes on instantly, or at least very rapidly, and is excruciating. It darts back perhaps to the

spine, causes the extremities and face to become cold, the pulse to be small, and the surface pale. It passes under the name of "spasm of the stomach." Very frequently, at the same time there is a large discharge of flatus through the oesophagus, which is usually inodorous. This pain frequently runs to the left shoulder and down the left arm, like the pain experienced in *angina pectoris*. I have known it run down both arms, and also run up the jaws and along the teeth. Sudden attacks of this affection are seen more commonly in women than in men. The pain is not always felt precisely in the situation of the stomach itself, but occasionally in the shoulder-blades and occasionally in the ribs—even in those which are not over the stomach, though the pain is dependent on that organ. In my own case, I have occasionally laboured under this pain severely, and I have been able to get rid of it by putting my fingers into my throat and discharging a quantity of sour stuff. When the pain in the ribs returned again (and which, if I had not paid attention to the stomach, I could not have believed arose from that organ), by making so slight an effort as hardly to be called vomiting, but sufficient to discharge a quantity of stuff like birdlime, I have invariably found it take the pain away. The pain is sometimes felt even at a distance—in the calves of the legs. Frequently, when there is much disturbance of the stomach, the legs fall into a state of violent cramp; the most common cause of which is the presence of acid in the stomach.

Cardialgia.—Besides this spasmodic pain, which comes for the most part suddenly, or if it exist constantly is attended with exacerbations, and is not increased by pressure, there is frequently inflammatory pain—not gastrodynia, but gastritic pain, so that the stomach is tender on pressure, and all ingesta produce great agony. A sensation of heat is induced there, and up the throat. In some cases you will find a throbbing of the epigastrium, a violent pulsation, which has been mistaken, no doubt, over and over again, for aneurism, and which patients themselves are inclined to believe is aneurism, because in this state of things they are much disposed to despond. This has been called *cardialgia*, and has been referred by Sauvages to a morbid sensibility of the part. Dr. Baillie wrote a paper on this subject in the first volume of the Transactions of the College of Physicians, in which he stated that he had been consulted several times on this affection, and which had been supposed to be aneurism, but he had not found it to depend upon that. He opened persons who died from some other disease while labouring under this, and found no-

thing. It is a common symptom, one which I have frequently been consulted upon, but you find no tumor. On pressing the part you feel the shape as usual, and you find at the same time a great depression of spirits, and more frequently than not various symptoms of disorder of the digestive organs. On looking over Sauvages I find he has described it as a dyspeptic symptom, and has referred it to a morbid sensibility of the arterial system of the part. He says it is certain that the gastric arteries and the aorta, although not affected with aneurism, yet in those who are constantly hypochondriacal and hysterical, acquire an exquisite sensibility, and produce this state. Occasionally the heat is far beyond what I have just mentioned; it is a burning pain, and patients usually speak of it as a burning sensation.

It arises in most instances from the quantity of acid produced there; and if there be any inflammation of the mucous membrane, the pain will be proportionately severe.

Intestinal symptoms.—The bowels are generally irregular, and for the most part they are torpid, but sometimes they are relaxed; in other cases you find an alternation of costiveness and relaxation, so that they are never right. The feces too are frequently unhealthy; frequently you observe them lumpy; but they are of various morbid consistency, and of various morbid colours, and frequently they are not of their usual smell. Sometimes there is a great want of bile, and sometimes there is even a degree of icterus. From the irritation of the stomach the urine usually becomes high-coloured, but at other times, especially when there is a great quantity of wind generated in the stomach itself, the urine becomes excessive in quantity, and pale, just as in asthma.

Symptoms induced in distant organs.—Other parts of the body, however, suffer as well as the gastro-intestinal, or, as it is used to be called, the alimentary canal. There is frequently headache, either general, or particularly in the forehead, and very frequently it is confined to one part of the forehead, confined to one brow; and sometimes it is intermittent, sometimes absolutely periodical. I have no doubt, however, that occasionally this headache does not arise from the state of the stomach; for disturbance of that organ may be produced by cold, or vexation of mind, and then when it comes to be very severe it will make a person sick. On the other hand it every day arises from things taken into the stomach which disagree with it. I mentioned formerly how hereditary this description of headache is, how frequently we see it in fathers and children, how frequently it occurs in many members of the

same family. Sometimes it will come on at regular, and sometimes at irregular intervals, disappearing perhaps after a certain number of years. It is so obstinate that I do not recollect curing a case of it, though I have tried every thing that could be devised.

Frequently in this disease there is confusion of mind; patients cannot apply themselves as they did before; they cannot read long, and I have known some obliged to give up study altogether. Frequently there is vertigo and heaviness of the head, and also sleepiness; but on the other hand, when the stomach is much deranged it is common for persons to lie awake; they find it impossible to go to sleep. There is frequently too a ringing in the ears—*tinnitus aurium*; and specks appearing before the eyes—*muscae volitantes*. There is frequently great sadness, great depression of spirits; patients are very restless and fidgety; and sometimes their temper is very irregular, so that you must take care not to say many things to them which at other times you may say with impunity. Voltaire, you will recollect, gives special directions to those going to ask a favour of the Prime Minister. He tells you to ascertain whether they have had their bowels opened in the morning, so much does temper depend upon the alimentary canal. He says you should always go to the *valet de chambre*, and ask if all has gone on regularly; and if you find that it has, then you may ask your favour. The heart also sympathises; there is frequently palpitation in these cases, and sometimes an intermittent pulse. Frequently there is night-mare, or terrific dreams. A partial consciousness, and yet an inability to make a voluntary exertion, comes on during sleep; but when patients can make an effort, they imagine they get out of this condition. Incubus is a very common symptom. There is frequently too a sense of great debility, which is felt particularly at the pit of the stomach. You hear patients complain of this every day; they say they feel as if their inside were all gone to decay. Sometimes there is a tremor of the whole body. The skin likewise suffers; it is generally dry and cold, but sometimes it is hot.

Now true dyspepsia—that is to say, those symptoms which depend upon the stomach performing its functions improperly, and which is worse, or indeed is only experienced after eating (persons sometimes have merely an inability to digest food, and are very well so long as there is no food in the stomach)—is attended with other symptoms. There is loss of appetite, vomiting, distant pain, and the other symptoms which I have mentioned; but you will frequently have these without

much indigestion. You will find persons complain of a great sinking at the pit of the stomach; they will have gastrodynia and pyrosis, and yet they will digest their food well—have no dyspepsia, although there is stomach derangement. They are very well when they take food, and only suffer when the stomach is empty. Some of these things are merely called indigestion. Some patients have none of these symptoms, and some may have one or other, or both together. Persons who suffer in this way frequently become pale and emaciated; they live many years, but they are never well; they are not ill enough to die, but their complexion becomes altered.

PHYSIOLOGICAL OBSERVATIONS.

By PROFESSOR MAYO, F.R.S. &c.

In every successive course which a lecturer delivers, he is likely to observe some fact or relation of his subject which had before escaped him. The following are some of the points in physiology, which I either saw for the first time in my last course of lectures, or thought I then saw more justly than before.

1. It is well known that the fossa in the acetabulum contains a cushion of fat for the purpose of protecting the round ligament from pressure. Upon examining the relation of the round ligament to that cushion, and its influence upon the motions of the joint, the following observations will be found to be correct. The round ligament is attached to the marginal or inner edge of the fossa in the acetabulum. The direction of its fibres, and the line of their attachment, is such that when placed upon the stretch it lies in the long diameter of the fossa. Its length is exactly equal to the long diameter of the fossa. In order to place it on the stretch, the thigh-bone must be rotated inwards. Its use is to limit the extent to which the thigh-bone can be rotated inwards. The ligament which limits this motion is placed within the joint (not behind it,—upon the analogy of the ligament which limits rotation outwards, and which is placed externally to and before the joint), in order that it may not impede flexion of the hip-joint. In a large proportion of cases of dislocation of the hip, the violence which forces the bone out of the socket twists it inwards: the round ligament, in these

cases, resists, and is torn before dislocation can ensue. The notch for the insertion of the round ligament is situated below the axis of the head of the femur, to withdraw the ligament from the vertical pressure of the trunk.

2. If all the ligaments of the knee-joint but the crucial ligaments are divided, and the tibia is held in such a manner as to prevent its rotation outwards, lateral motion of the joint is found to be as strictly prevented as before, and that in every position. By what mechanism is this accomplished?

The crucial ligaments of the knee-joint are oblique in their direction, so that the anterior, which descends obliquely inwards, may be supposed to act as an internal lateral ligament; and the posterior, which descends obliquely outwards, may be supposed to act as an external lateral ligament. But to act as lateral ligaments in any position of the joint, they must be upon the stretch in that position; to act as lateral ligaments in every position of the joint, they must be on the stretch in every position of the joint. This, in fact, is the case. The adjoined diagram will explain in what manner tension of both ligaments is preserved in all positions.

The diagram represents the knee-joint, for the sake of clearness, without the patella, and without a close apposition

of the articular surfaces, in the states of extension and flexion; together with the direction, expressed by dotted lines, of the crucial ligaments. The line A D represents the posterior or internal crucial ligament during the extension of the knee-joint. The curved line, D E, represents the segment of a circle, which is the point of insertion of the ligament A D describes during flexion. In a similar manner the line A B represents the course of the anterior or external crucial ligament, and the line B C the segment of a circle which the insertion of A B describes during flexion. It is evident that the posterior crucial ligament is kept constantly on the stretch, in consequence of the posterior surface of the condyles being made an arc of a circle, the centre of which is the point of origin of the posterior crucial ligament; and that the anterior crucial ligament is kept constantly upon the stretch through the flatness of the anterior and inferior surface of the condyles of the femur, and the corresponding flatness of the surface of the head of the tibia.

The same flatness of the inferior and anterior surface of the condyles it is which causes both the crucial ligaments to concur in limiting the extension of the knee-joint. If the surface, instead of being flat, were curved, as in the imaginary line D K, it is evident the

ligaments A D, A B, would allow of *flexion forwards* as well as of *flexion backwards*, or that there would be no check and support at the full extension.

The obliquity of the two crucial ligaments, in relation to each other, prevents rotation of the tibia at the knee-joint inwards. The internal lateral ligament has so remarkable a breadth and thickness in order to impede rotation outwards.

3. I believe that I originally pointed out the principle upon which the mitral and tricuspid valves close their respective auriculo-ventricular openings. This effect I shewed to be the necessary consequence of the exclusive insertion of all the tendinous cords derived from one fleshy column into the adjacent sides of two adjacent projections of the valvular membranes. The following diagram shews, however, more justly than the figures in my "Outlines of Physiology," the effect of the mitral valve in action. The two projections of the valvular membrane are, as it is well known, of unequal size. The projection, or flap, adjacent to the opening into the aorta, is much deeper than the other. The effect produced when the two flaps are drawn together, may be seen, upon a dissection of the heart, to be such as is delineated by the dotted lines in the adjoining diagram. The

mitral valve, in its action, not merely closes, or nearly closes, the retrograde passage towards the auricle, but is drawn aside in a remarkable manner from covering the channel towards the aorta. In the diagram, a continued line represents the valve when open.

4. In a perfect sacrum, the posterior arches of the three uppermost false vertebrae are complete. The arches of the two lowest are incomplete. Why this difference?

I find that the arachnoid cavity of the theca vertebralis terminates at the third sacral bone. As low down as the arachnoid membrane extends, does the water of the vertebral canal (which Magendie discovered to be contained between the arachnoid membrane and pia mater) extend. As low down as the water of the cord extends, is the support of a bony canal required to prevent its undue accumulation. The necessity of this support is shewn by the tumor which attends a spina bifida. The arches of the lower sacral bones are then not required to be completed, because there is no longer a serous cavity to support.

I may take this opportunity of mentioning, that in the autumn of 1831, I dissected with Mr. Partridge the third division of the fifth nerve in a specimen in which the bone had been softened by maceration in muriatic acid and water, for the purpose of examining the ganglion oticum and its branches, which is figured in the plates in Dr. Frederick Arnold's work, entitled "*Der Kopftheil des Vegetativen Nervensystems beim Menschen.*" It appeared to us that in that specimen the ganglion oticum did not exist. In another dissection, which I made in March last for the same purpose, the ganglion oticum was not to be found. The branches which Arnold supposed to proceed from it, appear to be derived directly from the third division of the fifth nerve, and principally from its ganglionless portion.

King's College, July 27, 1833.

MEDICAL JURISPRUDENCE—THE EXACT TIME OF BIRTH.

To the Editor of the Medical Gazette.

SIR,

MEDICAL jurisprudence has attracted much more attention of late years than

formerly, but certainly not more than it deserves; for there is scarcely any department of professional study which involves so many and such various points of high interest. The subject of the following communication may, at first sight, appear trivial, but it is curious, and may at some future time give rise to judicial investigation.

There is a well-known story of a dispute as to the exact day of the birth of a child, which took place *after* the house clock had struck twelve at midnight, *whilst* the parish clock was striking, but *before* St. Paul's had begun to strike. The signature of important documents on the day of coming of age is often of great consequence; but in the above instance the question of fact was one rather for a clock-maker or an astronomer to decide than a medical man, and I believe was properly determined by considering the metropolitan as paramount over the parish clock, and that over the one in the house.

The following case equally involves a question of date of birth, but it is one which must be decided solely by the physiologist.

On the Saturday evening a lady was in labour with her first child. The head and one arm were born two or three minutes *before* the clock at the Horse-guards struck twelve; there was a cessation of pain for several minutes, during which time the child cried and breathed freely. The rest of the body was not expelled till full five minutes *after* the clock had struck twelve. Was this child born on the Saturday or on the Sunday?

Certainly the birth was not *completed* till the Sunday; the child was still partly within the mother; the circulation was still kept up through the umbilical vessels; but I gave my opinion that the child was born on the Saturday.

I considered that the child had begun an independent existence. The fetal life had to all intents and purposes ceased, and respiration, a function incompatible with the condition of a fœtus, had freely commenced. The umbilical cord will go on pulsating for many minutes after an infant is completely in the world, crying and kicking, unless compressed artificially; and yet no one will say that a child is not born till we choose to take the trouble to tie the navel-string. The child would not have been damaged if it had remained for

hours, or even days, with merely its head and arm extruded; it could have been fed; in Catholic countries it might have been baptised, even without "*le moyen d'une petite canulle*," as recommended for unborn babes by the pious casuists of the Sorbonne, and so humorously alluded to in *Tristram Shandy*.

The question as to whether a child was born alive, however momentary its existence, often so important in cases of tenancy by courtesy, is different, but may become mixed up with the above: as, for instance, a child's head may be born; the child may cry and breathe, and yet die before the rest of the body is expelled. Transmission of property may be seriously affected by the decision as to whether such child was or was not born alive.

As I believe this is a new point, and much may doubtless be said on both sides, I should be much gratified by the opinion of any of your readers who have applied themselves to the investigation of medical jurisprudence.

Your obedient servant,

C. Locock, M.D.

Hanover Square, July 24, 1833.

PLACENTAL CIRCULATION — CÆSAREAN OPERATION.

To the Editor of the Medical Gazette.

SIR,

THE following paper is offered to you on account of its having relation to the subject of placental circulation, which has been lately so much under inquiry. If you consider it worth a place in your publication, it is at your service for insertion.—I have the honour to be, sir,

Your obedient servant,

J. F. MARSON.

10, Montague-Street, Russell-Square.

Mrs. C. advanced to the eighth month of gestation of her first child, was seized with labour on the 18th of last month. After ascertaining that the head was presenting, and in the right position, I retired for a time to another room: during my short absence, she had a violent attack of uterine action, and from having a capacious pelvis, and being but in the eighth month of pregnancy, the

ovum was quickly expelled entire, the membranes, with the placenta attached to them, encircling the child, and the latter floating in the liquor amnii. When the membranes were ruptured, the child did not breathe well, and as the circulation was going on rapidly through the funis, it appeared to me at the moment to be advisable not to interrupt it: for nearly three-quarters of an hour, the child did not expand its chest oftener than once in five minutes: from that time its breathing improved, and at the end of an hour was carried on properly. I then divided the funis, which was still circulating blood freely, and was careful in observing, during the whole time that *no hæmorrhage* took place from that part of the placenta which had been attached to the uterus.

Although the pulsation felt in the umbilical cord was only evidence that the blood was passing to the placenta, still I think it may be safely concluded that it was returned to the child, or its vitality would have been destroyed before the lapse of an hour.

I have brought this instance forward to shew the independence of the circulation of the fœtus, and for the purpose of suggesting that the Cæsarean operation might probably be successfully performed, at a greater length of time, after the death of the parent, than is generally supposed. Happily this operation is but rarely required; but as it has the sanction of some of our first writers, and was by law enforced by the ancient Romans, when death took place during pregnancy, it is worth while to consider at how great distance from the apparent death of the mother, it may be resorted to with a fair prospect of success.

In the second book of Ovid's *Metamorphoses*, we find that Æsculapius was removed by the abdominal section, and that Apollo was the operator. Virgil represents Lycas, one of his heroes, in the tenth book of his *Æneid*, as having been born in this way. Pliny, in his seventh book, states that Scipio Africanus, Cæsar, and Manilius, were removed by incision; and two other persons are spoken of in Rousset's treatise. Some of these examples are cited from works of fiction, and must be estimated accordingly; perhaps no great reliance ought to be placed on any of them, not even on Pliny; for whoever will take the trouble to read three or four pages

of his seventh book, will readily see that he makes many very ridiculous assertions; but he is supported in his statement concerning the birth of Scipio by Terullian, and by Festus in his account of the birth of Cæsar. Nearer the present day, we learn that Robert the Second of Scotland was born after the death of his mother, who broke her neck in hunting; and that,

—“Macduff was from his mother's womb
Untimely ripp'd.”

These instances, as well as many others I could quote, will be sufficient to shew that the operation has been frequently undertaken, and that the children have lived; but in none of them is it noticed at what time the operation was performed after the mother's death, except in the following, on which the utmost reliance may be placed:—Flajani, of Rome, removed a fœtus by the Cæsarean section *an hour* after the death of its parent, who died of fever in the seventh month of pregnancy. The child breathed for ten minutes, and then died.

In the 12th volume of the *Medico-Chirurgical Transactions* is recorded a case of Cæsarean operation, performed by Mr. Green. The woman was in the ninth month of pregnancy, had been run over by a stage-coach, and died twenty minutes after the accident. Mr. Green began the operation *thirteen* minutes after her death, and the child lived 34 hours after its removal from the uterus.

Burns says, without giving the name of the operator, “a woman died of dysentery, of two months' duration, in the end of pregnancy, and by the operation, performed about *twelve minutes* after death, a living child was extracted.”

A case bearing on the same point, although not one of abdominal section, is related by Dr. Jackson. A woman, who had been for some time suffering from pectoral disease, died suddenly during labour: the child was sufficiently advanced to allow of being removed easily by the forceps: this was accomplished *a quarter of an hour* after her death, and in something more than another quarter of an hour, the child began to breathe.

Before closing my letter, I beg to recur to the case that has been the cause of these observations:—

1. Was the blood actually conveyed,

as I have supposed, from the child to the placenta, and back again to the child; or was the pulsation in the cord merely an impulse given to the blood contained in it?

2. Allowing that the blood did pass again to the child, did it undergo any beneficial change in its passage through the placenta, and, if so, what was that change? was it of the kind that takes place in the fœtal state, or such as it undergoes in passing through the lungs, when respiration is established?

3. Were the inspirations at intervals of five minutes, for nearly an hour, sufficient to keep the child alive?

CONTAGION IN ERYSIPELAS.

To the Editor of the Medical Gazette.

SIR,

I AM induced to trouble you with a few remarks on a subject which has long engaged medical attention, and one which still seems of an inexhaustible nature: I mean that of contagion. Every man comes forward with his important facts either for or against this long-agitated question, and had it not been for the “Brief Statement of Facts,” by your correspondent, Mr. Bury, of Farnham, on the contagious nature of erysipelas (page 533), I should not, perhaps, have ever troubled you. Your correspondent appears so blindly wedded to the subject of contagion, that, like every good husband, he sees only the perfections of his spouse: but I draw very different conclusions from his own premises, and cannot see in the cases he adduces a single instance of the disease being contagious, or communicated from person to person—and “this, too,” he says, “not in the contaminated atmosphere of a crowded hospital, but in the pure air of the country cottage:” on this observation I accordingly found my remarks, and draw very different conclusions. I think, had Mr. Bury observed more closely, he would not have favoured the medical world with his lucubrations on the subject: but as he has, he is bound to give us some stronger proofs of the contagiousness of the disease. He must explain how this contagious disease did not spread beyond the walls of the cottage. Had he himself been affected with it—had he commu-

nicated the disease to any of his family, or to any of his patients whom he daily visits—or had any of the friends of the Parfitt family had the disease—then I would have been convinced that there are “instances so palpable of erysipelas being communicated from one person to another; and that this one fact would have been worth a thousand speculations.” As your time and pages, sir, are valuable, I will be brief to state what you and every one must know, who have given this subject any consideration, that no one proof is furnished by Mr. B. of there being any thing like contagion in the instances produced. Suppose the cottage situate in the vicinity of a marsh, and that ague had appeared in Wm. Parfitt, it is probable Ann, the father, Mary, Daniel, and David, would have had the same disease successively; but who would have ascribed this to contagion? Reverse the case, and suppose it one of small-pox, or any other disease which the profession unanimously acknowledges to be contagious; I ask, would it have been confined to the pure air of the cottage? I am much disposed to think Mr. B. must have overlooked some powerful cause connected with locality, productive of this endemic to which the Parfitt family were continually, for a time, exposed. Some half century ago this would have been quite sufficient to have determined this as an example of contagion, but the doctrine is now somewhat better understood; medical men assume the right to think and observe for themselves; they are less fettered by the authority of great names and scholastic dogmas, than in those days when the academical dictum would have pronounced any febrile excitement contagious, and which would have been implicitly taken for a fact, by the profession at large, and “worth a thousand speculations.” Had it been Mr. Bury's lot to have witnessed many tropical suns pass over his head, he would have had an opportunity of observing the effects of locality in producing disease of this description, as well as others of a very different type, without the agency of contagion. He would then have arrived at conclusions very different from what this isolated instance affords.

Were your pages, sir, as free as my time and inclination, I could willingly extend this particular topic. I could shew

that the circle of contagion is now much limited, while that productive of endemic disease is greatly enlarged. But should you think the foregoing worthy of your notice, I may on some future occasion refer to this subject. My object is to arrive at truth, and to elicit information on a point of general interest to mankind, without meaning to detract from the merits of Mr. B. as an observer, but just to call his attention to some points which he may have overlooked, and which may not be unworthy of his reconsideration.—I am, sir,

Your very humble servant,

JOHN ELLIN, M.D.

Newark, July 27, 1833.

ANOTHER REPLY TO THREE QUERIES RESPECTING CHOLERA.

—

To the Editor of the Medical Gazette.

SIR,

IN a late number of the Gazette the following questions are proposed by one of your correspondents, viz.:—

1. “Have the limbs of persons dead of cholera been observed to move, elsewhere than at Tipton?”
2. “Have oily dejections been noticed in cases of cholera?”
3. “What are the powers of mercury in the complaint? how are they displayed, and in how short a time after its employment?”

As there unfortunately appear some indications of a second visitation of cholera in these islands, I think every one who has had experience of the disease is bound to afford whatever information he possesses regarding its symptoms or treatment. Having been a witness of some thousands of cases in the chief cholera hospital of this city, in which I was a resident medical officer for nearly four months, I deemed it a duty to lay before the profession what I had learned on the subject; and I beg leave to reply to your correspondent's queries by a few short extracts from my “Notes on Malignant Cholera, as it appeared in Dublin,” published in the sixth and seventh numbers of the Dublin Journal of Medical and Chemical Science.

Extract in answer to Question 1.—

"For some time after the circulation and respiration have ceased, the toes are affected with spasmodic motion; I have observed them twitched at intervals of three or four minutes, for six hours after apparent death."

Extract for Question 2.—"The thirst and vomiting continue unabated, while the purging often subsides after three or four rice-water evacuations; or there begins to be passed from the rectum a fluid resembling water in which meat had been steeped, with an oily film here and there over its surface."

With respect to the third question, I fear a satisfactory reply would demand too large an extract; but I may state, that calomel is almost the only medicine on which I rely; that I have exhibited it in large quantities, not unfrequently to the extent of 900 grains in 78 hours. I did not observe in a single case where I gave calomel any of the manifestations of the poisonous action of mercury. The mouth became slightly sore on the second, third, or fourth day (more frequently on the fourth than the second), and the very moderate flow of saliva rarely continued beyond four or five days more. Calomel stopped the vomiting at that stage or period when such effect became desirable. In a word, mercury, in my experience, produced decidedly salutary results, and none others. In one species of cholera mercury often failed to do any service.

Your obedient servant,
SIMON M'Coy.

A NEW METHOD OF PREPARING MEDICINAL PRUSSIC ACID.

To the Editor of the Medical Gazette.

SIR,

I HAVE to beg your attention to the subjoined formula* for the preparation of

medicinal prussic acid, by the extemporaneous decomposition of cyanuret of potassium; a plan which, for its simplicity and perfection, is probably destined to supersede the five very uncertain methods now in use. The medicinal solution made by it (of which the accompanying phial contains a specimen) is obtained *always of the same strength*; nor is it an insignificant recommendation, its being much less liable to spontaneous decomposition than the sorts made in any other way.

There has been an impediment in the adoption of such a formula, in the delicacy of the cyanuret of potassium; no plan heretofore having been discovered for its formation in a state of purity. The few specimens of this salt which I have been able to collect, have all exhibited a variety of hues, depending on particular contaminations; and in some instances they were found to contain large quantities of carbonic acid. The prussic acid made with them was usually, in consequence, of a deep yellow colour; but at times it was obtained green, and brown, and blue.

The accompanying cyanuret of potassium is pure, and I believe the first specimen ever obtained in a state of purity. By analysis I have found its composition to be,

Cyanogen,	3.25	×	8	=	26
Potassium,	5	×	8	=	40
	8.25				66.0

and that of anhydrous prussic acid being

Cyanogen,	3.25	×	8	=	26
Hydrogen,	1.25	×	8	=	1
	3.375				27.0

We have, of course, in every 66 grs. of cyanuret, an equivalent for 27 grains of absolute acid; and this number being allotted, in the new formula, to 27 drachms of liquid, every 60 minims of the medicinal prussic acid will contain precisely one grain of the strong medicine. The relative strengths afforded by the known formulas stand thus:—

* Take of Cyanuret of Potassium, 22 grains; Tartaric Acid cry-tals, 50 grains; Distilled Water, 6 fluid drachms; Rectified Spirit, 3 fluid drachms; in a phial capable of containing eleven or twelve fluid drachms. Dissolve the tartaric acid in the water and the spirit, previously mixed together, and suffered to become quite cold; then add the

cyanuret of potassium, and immediately close the phial with a sound cork. After occasional agitation during ten minutes, secure the cork and set the phial aside, for the supertartrate of potass to precipitate,—when the clear solution may be decanted for use.

Plan by	Formula by	Number of Grains of absolute Prussic Acid in 60 Minims of Medicinal Solution.	
		Real.	Estimated.
Scheele.	Scheele.	1½	8
Pharm. Dublin	Pharm. Dublin.	1 or 1¼	1½
Gea Pessina.	Henri.	unknown.	20
Proust.	Pharm. Gallica.	1 or about.	1½
(both ascribed to Vauquelin).			
Vauquelin & Gay Lussac.	Magendie.	7	7
	Robiquet.	20	20
New Plan.	New Formula.	1	1

This table will explain the reason why one grain in a fluid drachm has been adopted for the new formula: in the first place, it is about the strength which experimentally results from the only process at present sanctioned by either of the British Pharmacopœias; it is also near to that of the medicinal acid usually called Vauquelin's; and from Scheele's it differs by about half a grain, on that side which will be a guarantee against a careless dispenser of prescriptions doing mischief, should he mistake the newly-introduced medicine for his. In addition to this, it has been thought to afford facilities for the correct estimation of a dose.

It only remains for me to say, that my manner of preparing the pure cyanuret of potassium has been communicated to the gentlemen officially engaged, in London and in Edinburgh, in compiling the new joint Pharmacopœia; with whom the question must for the present rest.—I am, sir,

Your obedient servant,
RICHARD LAMING,
Surgeon.

CASE OF ENLARGEMENT OF THE TONGUE.

To the Editor of the Medical Gazette.

SIR,

HAVING lately read an account of a case of great enlargement of the tongue, re-

ported in your Gazette by Mr. Taynton, I will endeavour, as far as I can recollect, to sum up the particulars of a similar case which occurred to me some some years ago—in October, 1825. You will oblige me by inserting it in an early number.

I am, sir,
Your obedient servant,

J. COLLIER,
Mem. Roy. Coll. of Surgeons.

Brackley, August 4, 1833.

Mrs. P., ætat. 40, and in the last month of pregnancy, felt one day an uneasiness in the mouth. The following day I was requested to visit her, and found that she was unable to close the mouth completely; and on examination I perceived the sublingual gland on the right side to be much enlarged and painful, the flow of saliva increased, and difficulty experienced in swallowing. Her speech was altered, but her breathing was not much affected.

I directed gargles to be used, and leeches applied outwardly; added to which I gave aperient medicines. The next day I found the gland still swollen, and likewise that side of the tongue, which gave the patient's mouth a distorted appearance. The jaws were still more separated; the speech could scarcely be understood.

In order to give relief, I made two incisions along the side of the tongue, from which flowed about a tea-cupful of blood. The patient felt somewhat relieved by this treatment. This was done in the afternoon. But when I saw

her again the following morning, the whole of the tongue was swollen to such a size as to alarm every person, and threaten the almost speedy suffocation of the patient. A large portion of it protruded from the mouth, and separated the jaws to their full extent. At this time articulation was impossible, and also deglutition. I now resolved to make an incision along the whole course of the raphé, sufficient to procure a free bleeding. The quantity of blood obtained was about fourteen or sixteen ounces, and in a very short time I had the satisfaction to find the patient very much relieved by it.

After this second operation the tongue soon became diminished in size, allowing the patient to breathe more easily, and in a day or two the jaws could be more approximated to each other.

But even now, during this interval of ease, the peculiar condition of the patient was still a cause of much anxiety, though she was able to speak a little and swallow liquids; for, instead of finding rest and becoming composed after this severe trial, symptoms of labour began to come on, and in the course of a few hours delivery took place. Nothing particular occurred in the labour, with the exception of the placenta being retained a little longer than usual.

During the night she slept occasionally, and the next morning appeared as well as I could reasonably expect.

The case went on very well; the tongue did not shew any disposition to enlarge again; in a few weeks the patient recovered, and, I am happy to add, is at this time alive and quite well.

What gave rise to the enlargement, I could not satisfactorily ascertain.

SIMPLE MODE OF REDUCING A DISLOCATION OF THE SHOULDER.

To the Editor of the Medical Gazette.

SIR,

IN the No. of your journal for the 25th May last, you have given a paper (extracted from the Dublin Journal) by Dr. Crampton, on the Pathology, &c. of Dislocations of the Shoulder-joint, which paper I consider fraught with interest to the surgical profession. That

part of it to which I am now going to refer relates to dislocation forwards, or under the pectoral muscle; and I am of opinion that the case which I am about to state will be another proof that this dislocation is frequently of primitive occurrence.

Having read with very great care Dr. Crampton's remarks, and being forcibly struck with the case of the Hon. Col. Gore, related by Dr. C., I determined upon pursuing the same practice in the first dislocation of this nature that might present itself to me; and I certainly had an earlier opportunity afforded me than I could possibly have anticipated, for on the 29th June (not longer than a month after reading Dr. C.'s paper), I was sent for in great haste to R. W., æt. 33, who had got drunk, and fallen upon the pavement; and on my arrival at his house, about an hour after the receipt of the accident, I found him lying in bed on his left side, with the head of the right humerus dislocated forwards. The head of the bone was not only felt, but seen distinctly, in its new situation, my patient not being a very stout subject.

I ordered him to be taken out of bed and placed upon a chair, and while the spectators were busy chattering, and preparing towels and strength, which they considered indispensable, I was examining carefully the exact state of the joint; and having made up my mind to try first Dr. C.'s plan, as practised upon the Hon. Colonel, I took hold of the patient's wrist with my right hand, while I placed my left, clenched, in the axilla, and having made the slightest possible extension, I suddenly drew the arm across his body, in the direction of the left hip, when I felt the head of the bone glide smoothly into the glenoid cavity. This was attended with so little trouble, that the bystanders were surprised at the easy reduction, and seemed not a little disappointed that their towels and strength should have been disregarded.

I am not able to state in what direction the force was applied that dislocated the bone, for no person was with the man at the time the accident occurred, and he, being quite drunk, knew nothing, of course, about how it happened.

I will only further add, that I think the surgical profession is highly indebted to Dr. Crampton for publishing his pathology of this dislocation; and, for my own part, I take the present op-

portunity of tendering him my warmest thanks.

Should you consider these few hurried remarks worthy a place in your journal, they are very much at your service.

I am, sir,

Your obedient servant,

DAVID BELL, M.D.

West Tower-street, Carlisle,
August 3d, 1833.

VALUE OF SCIENTIFIC PURSUITS IN CONNEXION WITH THE STUDY OF MEDICINE.

To the Editor of the Medical Gazette.

— "Magnisq. agitant sub legibus rerum."
VIRG. G. iv. 154.

SIR,

In the growth of the human mind there are three stages through which it passes, and then it arrives at maturity. This mental passage, which is peculiar to the individual man, is common also to man as a species.

First, the mind in its simplest state beholds and observes facts, collects many of them, and then acts upon the knowledge of these acquired data. This collection, when extensive, constitutes the man of experience, who, though he is wise in many particular instances, yet knows not how to include many particulars within one general whole. "All justifiable practice, indeed, in every kind of subject, is founded in experience. Yet the man who acts from experience alone, though he act ever so well, is but an empiric or quack, and that not only in medicine, but in every other subject." Now the empiric is a luckless wight, lost and bewildered within a fleeting multitude of infinite particulars; and so, like an ephemeral insect, he quickly passes away.

In the second stage of the mental progress, facts are still observed, but no longer acted on at once. The observer notes the facts, and meditates upon them, but then seeks to discover their relation with contingencies collateral or future, and accordingly forms an opinion as to the possible or probable operation of present data. He now substitutes *opinion* for reality; and as this opinion is founded in possible contingencies, so it is that most opinions are

possible or probable, but seldom absolutely certain. From opinions formed from present data as to future or collateral events, the mind begins to reason back from opinion to conjecture; and in this act of mental retrogression, to modify, pervert, distort, or perplex, the most simple and obvious circumstances. This second stage of mind is often the curse of science; it is scientific polemacy. To it is to be ascribed all the dim hypotheses which have enveloped the learned world "in double night of darkness and of shade;" to it is to be imputed the scholastic theology of the middle ages, the cabalistic theology of the Jews, and the false theories concerning astrological divination, alchemy, and necromancy, as well as the later theories concerning the soul, and life, and the cause of life.

Each pedant sage unlocks his store
Of mystic, dark, discordant lore,
And points with tottering hand the ways
That lead us through the thorny maze.

And now, lastly, of the third stage of its progress, in which the mind resumes its primitive simplicity, and again observes and acts upon nothing but facts. But its action and powers of observation are now matured, and guided moreover by the experience of its past errors when under the illusive influence of conjecture, and opinion, and remote analogy. It now denotes every particular fact, and accumulates every combination of facts at one common centre of reference. It analyses, compounds, and divides and subdivides, them into many elementary materials, and deduces from every element, and from the minutest particle of each element, new truths and fresh discoveries, which are now true because they are demonstrable, and now permanent because they are analytically tangible. Every part and particle is shewn to subsist under the control of certain laws, and these laws are found to include within their jurisdiction many diverse conditions of matter, which several laws again are found to submit to the superior rule of some one single, grand, and universal principle. Nature hereby becomes a magazine of truths, which is open to all, and from which, as from the kingdom of heaven, may be drawn forth "things new and old;" *old*, as being included under known laws, and *new*, as being discovered to be unexpectedly inclusive under

the laws already known. " 'Tis thus only that we recognize art, and that the empiric quits his name for the more honourable one of artist, when to his *experience* he adds *science*, and is thence enabled to tell us, not only *what* is to be done, but *why* it is done; for art is a composite of experience and science, experience providing it materials, and science giving it a form."—*Harris' Hermes*, b. iii. c. iv.

The mind, which has been disciplined to think only according to the obvious necessity of things before it, is the consummation of human intellect and reason, and is something more than a mere abstract principle incapable of practical utility, since it forms equally the scientific philosopher and the sound practitioner. Aware of the accidents of life, the man of intelligence, so accomplished, never prejudices; conscious of his own liability to error, he is not hasty in opposing or directing the opinions of others; and, knowing the imperfection of knowledge, he acts as much as possible upon nothing but what is known. Being well instructed in the duties of his station, he is always alert in the exercise of his talents, and foremost at every point of exertion; he is nobly ambitious of being esteemed for discharging fully those offices with which he may be invested. Upon the ground of solid information, he earns the title to excellence in his profession from the common consent of mankind, and snatches not at those honours which are acceptable only when they are bestowed. This sober and trustworthy conduct, the result of right reasoning from right principles, characterizes the practical philosopher, and marks the passage of his life. The days of the longest life are not many, and those of the busiest portion of it are but very few; and yet it is during this short season of business or action that the peculiar character of the actor is projected. Who would not anticipate that season by the previous rectification of the mind, so as to bring visibly into play the outward operation of inward truth; and to demonstrate that mind, like matter, is subject to laws, but that mind, superior to matter, holds the ascendant, by recognizing the laws and the utility of the laws to which it freely submits?

MEDICULUS.

July 20, 1833.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

RASPAIL'S ORGANIC CHEMISTRY.

Nouveau Système de Chimie Organique. fondé sur des Methodes Nouvelles d'Observation. Par F. V. RASPAIL. *Accompagné de douze planches gravées, dont six coloriées.* Paris. Bailière.

THIS is a work which will make its way in the world, in spite of its rude, rough, and uncompromising tone: it will have to encounter many an obstacle, no doubt, in its progress, but its merits will ultimately bring it through. Its history is curious: we have heard of a Cervantes, and a Smollett, and others, sending forth works of imagination from a prison; but here is a work of science, and one of consummate research, the product of the durance vile of its author. M. Raspail, though little known to the British public, has earned for himself an ill-fated celebrity in France, from the stubborn *liberality* of his opinions, both in politics and physics; the former of which being more tangible than the latter, and more cognizable in the social arrangements of the French form of government, gave the poor philosopher a passport to a gaol, with liberty to amuse himself there as he best could. The book before us is the production of this uncomfortable retirement; and even were it not dated from a prison, the strain of bitterness in which its author shews how ill he is at ease with the world, would pretty well serve to point out the locality of its origin. The dedication is curiously characteristic: it is to the memory of the Abbé Eysséric, "*mon pauvre maître*,"—who, "had he dwelt in Paris, would have merited to be of no academy," &c. and the author subscribes his name, and sets it in the title-page, doggedly stripped of even the shadow of a title. All this is very painful, and greatly to be regretted; especially where the person for whom we feel is undoubtedly a man of talent—of education—of virtue, but of a very obstinate and intractable kind.

In point of time, M. Raspail is not an author of any considerable standing: his earliest contribution to vegetable

physiology is not dated farther back than 1825; yet, since then, few have been more indefatigable than he, or have published, in various journals, a greater number of memoirs. In controversy he has had many a battle, and he can reckon among his adversaries several great names—Dutrochet, Orfila, Arago, among the number. It could hardly be expected that one who exhibited so little courtesy to others, and so little deference to eminent persons, should have more than bare and tardy justice measured out to himself. Accordingly we find him complaining that it was seven years before he obtained even common civility from the Institute, and then only owing to the weight and impartiality of M. Biot. This gentleman, he says, did him justice publicly, in the Academy of Sciences, and paid him a high compliment on the exactitude of his researches. Tiedemann also makes honourable mention of M. Raspail, (when treating the subject of the pretended spermatie animalcules of vegetables,) and copies in detail most of his argument refutatory of Brogniart's and Robert Brown's doctrine: and so with others whose impartiality the author rather coldly acknowledges in certain parts of his book.

The System which M. Raspail has now given to the public, is the result of those numerous experiments and observations which, in a detached form, have been already published and submitted to the test of criticism. It is not a mere compilation of his papers which we have here, nor a selection from them, thrown into a form sanctioned by authority: not even the name of Berzelius can induce Raspail to adopt the classification recommended by the great Swedish chemist: our author generalises and simplifies for himself, and we must add that his reasons are abundantly cogent and convincing. As to the division which has hitherto commonly prevailed, of organic chemistry into vegetable and animal, he tells us that however excellent it may be with reference to physiology, which has only to do with the functions, it is and can only be in the actual state of science engaged in the analysis of molecules—a mere fancy, on which nothing solid can be erected: it entails the absurd necessity of separating things the most analogous, and combining those which are least so. “Berzelius,” says M. Raspail, “keeps up a dis-

inction between vegetable and animal substances, without, however, adopting a dichotomous classification. In his *Chimie Végétale*, which has latterly appeared, we find this sort of succession in the substances of which he treats: the vegetable acids, the vegetable alkalis, starch, gum, sugar, gluten, oils, resins, extracts, colouring matter, and then an analysis of the organs of plants in their botanical order; the whole wound up with an account of the products of vegetable decomposition. This is neither a system nor a classification: it is only a voluminous table of contents; yet, considering the disdain which its author always professes for results obtained by the alliance of physiology and chemistry, we cannot blame him for the method he has taken.”

We cannot say, after all, that we are quite satisfied with M. Raspail's own arrangement, though we doubt not it is the best that has hitherto been suggested. It may be considered as comprehending a four-fold division: the organic elements of tissues, animal and vegetable, are divided into, 1st, those which compose organized substances; 2dly, those forming substances which the author styles *organisatrices*, including milk and sugar; 3dly, those forming organizing substances—such as the oils, resins, bile, and saliva; and 4thly, those which go to compose organic substances. The earthy bases of the tissues are then considered; and this includes the whole of the animal and vegetable kingdoms, as treated of in M. Raspail's system.

One of the most prominent principles of the author's method—or that in which his “New Methods of Observation” may be said to consist—is the contemplating every object and every phenomenon in several points of view—throwing upon them light derived from various sources. “Nature,” as he very well observes, “is neither exclusively a chemist, nor a botanist, nor a zoologist, a mineralogist, or a physiologist: she is not parcelled out into scientific compartments; she does not proceed according to any classifications or artificial arrangements; she is unique in her diversified combinations. How absurd, then, is it to study those combinations in a single aspect!—yet it is owing to this chiefly that so much error, so much miscalculation, so much loss of time has been incurred in the proceedings of the

several sciences about nature. The truly philosophical course which must be adopted, if we mean to come to any thing like positive results, is this—to borrow from each science all that it can contribute towards ascertaining a fact, or recognizing a law. Nature, for example, having deposited certain substances within the bosom of certain organs, we should interrogate anatomy for the means of being better acquainted with those organs; and when once we have come to this acquaintance, then should we call in the aid of chemistry, with its re-actions and processes. If the organs are too minute to be comprehended by our unassisted senses, we must invoke the aid of magnifying glasses combined in the microscope. Physics will teach us to follow the course of the luminous rays, and to allow for the effects of reflected and refracted light; and we have even frequently to transport our laboratory to the *porte-objet* of our microscope. Carefully, then, must we examine the several component parts of our object: we must take it in its greatest state of purity; and having perfectly assured ourselves of its characters and its re-actions in that state, we can the better divine its properties in combination." It is, in short, the general rule—the *soul*, as he calls it in another place—of his system, "that the isolated study of any property, the study of any body under a single aspect, with whatever cleverness, whatever conscientiousness, the observer may proceed, can only betray him into false inductions."—"For some years," says M. Raspail, "have I never ceased to follow up and to apply this simple and rational method; and such have I found to be its efficacy, that, without laboratory, without instruments, without protection, and sometimes without resources, it has never ceased to be fertile in results, which, after much persecution and outrage, have been at length adopted on all sides."

As a specimen of the freedom with which the author treats some of the fashionable doctrines of the day, we extract what he says respecting *endosmose* and *exosmose*—terms which he says might be very well superseded by the old familiar *imbibition* and *exudation*, or *transpiration*, &c. The affected nomenclature of certain modern philosophers seems, by the way, to be M. Raspail's aversion.

Endosmose and Exosmose.

"In the year 1827 Dutrochet announced that a liquid of a certain density, enclosed in an animal membrane, would attract a less dense liquid divided from it by the membrane. Let there be, said he, a glass funnel terminating with a tube, and let the mouth of the funnel be covered over with an animal membrane glued to its sides; or take the cæcum of a fowl, and insert into its opening a straight tube, not a capillary one; if we now plunge it into water, either the funnel or the cæcum having within them a fluid denser than water, the latter will be attracted, or rather pushed, as it were, by a force *à tergo*, through the membrane, and the fluid within will presently reach the top of the tube and run over; this is *endosmose*. If, on the other hand, the enclosed fluid be less dense than the water, it will be attracted out into the surrounding water, and the funnel or cæcum will be left empty; this is *exosmose*."

"It seemed to me that I had so often observed the contrary, that I hastened to repeat the experiment anew, with a certain number of liquids more dense than water, such as solutions of salts, &c., and they completely contradicted the fact of Dutrochet. [M. Raspail here refers to his articles on the subject in the *Bulletin des Sc. Naturelles*.] M. Dutrochet presently replied to me, by limiting his general law, and applying it to no more than a certain number of organic substances. Gum arabic and albumen he cited as particularly proper to attest the phenomenon. This explained the whole matter; the new law was now clearly nothing more than the law of imbibition; for gum arabic and albumen, rudimentary tissues, do not pass through organized membranes, while, on the other hand, they have a strong affection for water, by which organized membranes are permeable. Now if you put albumen into the cæcum of a fowl, terminating in a tube of glass, and plunged into water, what takes place? Why, the cæcum in the first place will imbibe the water; the albumen will then do the same; and this cannot take place, of course, without an augmentation of its volume, and the occurrence of the other phenomena just now described."

"Let the cæcum be filled with alcohol, and plunged into water; the alcohol,

not passing through organized membranes, will become saturated with the water, which does pass, and so its volume will be augmented. In like manner would it be with sulphuric acid, had not this fluid the property of rapidly disorganizing the tissues. Again, replace the membrane at the mouth of the funnel with a piece of very thin free-stone; put oil into the funnel, and plunge the whole into alcohol or ether. The alcohol or ether passing through the pores more rapidly than the oil, will soon add to the bulk of the fluid within. In fine, let the gum, in place of being dissolved, be introduced into the funnel in masses; it will presently begin to dissolve; or if you put quick lime in the funnel, it will be slaked, &c.

"The phenomena, therefore, differ in no respect from those of imbibition; and the *endosmometre* of M. Dutrochet can only be considered as a simple and amusing apparatus for exhibiting well-known appearances. Accordingly we find that the *great law*, the *discovery* of which was so much admired by the Institute, has successively fallen through the hands of reporters, and the author himself, from the rank of a law of *general physics*, to one of *animal or vegetable physiology*."

In the preliminary matter of the volume there is an excellent account of the author's processes, in the little and in the large way: the former comprehending some valuable remarks on the structure and use of the microscope; and, by the way, it deserves to be mentioned that most of the observations on which M. Raspail prides himself, he informs us were made with a two-frane simple microscope. The reader will, perhaps, remember that the beautiful observations of Swammerdam were, in like manner, made with perhaps even less assistance from art—with a common magnifier.

We do not, nor could we in a short notice of this kind, attempt to give any thing like an account of the particular doctrines of the author. So many curious and original passages struck us in the perusal of the volume, that though we began by marking passages suitable to be extracted, we soon, in consequence of their extent, gave up the design in despair. We cannot, however, conclude without strongly recommending all those of our readers whose studies are at all directed to the interesting pursuits of

organic chemistry, to avail themselves of the labours and the guidance of Raspail: they will find him, we think, both a steady and intelligent, as he assuredly is a sturdy, guide.

MEDICAL GAZETTE.

Saturday, August 10, 1833.

"Licet omnibus, licet etiam mild, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

COLLEGE OF PHYSICIANS.

THE document which we subjoin will render it apparent that the objections we have, at various times, taken to some important points in the present constitution of the College of Physicians, have found an echo in the sentiments of those more immediately concerned. That we are, and ever have been, among the truest friends of the learned body in question, none, we believe, will dispute, except those whose intellectual vision is obscured by that kind of haze,—the result of their own mystifications,—which seems to surround all our corporate institutions, and to prevent their inmates from perceiving the changes which are daily taking place in the world around—or, at all events, from being able to appreciate them duly. So far are we from desiring to abate one iota of the just privileges enjoyed by the College of Physicians, that we are most anxious to see them increased: but, then, we would have their influence extended to the general body of physicians, not concentrated, as at present, in a few, to the exclusion of others quite as deserving. We would have the jurisdiction of the College not confined to a comparatively small number of individuals, and contracted within the range of seven miles from the metropolis; but would have it embrace all the physicians in England—regulating its own faculty in every

town and every county : just in the same manner as the allegiance due to the College of Surgeons, though purely honorary and not compelled by law, is yet acknowledged as much in the most distant quarters as in the immediate vicinity of their Hall. We are aware that there are men in the College of Physicians who regard all censure as presumptuous, and shrink from all change as productive of anarchy and ruin ; but we also know that there are others who mark the signs of the times with a discerning eye, and who perceive the necessity of some timely reformation. To the former we have no arguments to address, for to none would they listen ; but to the latter we appeal in friendly though most earnest entreaty, to take advantage of the opportunity which is afforded them, and to set their house in order ere yet it be too late.

The present bye-laws, regarding the division of qualified physicians into Fellows and Licentiates, are highly objectionable. It is monstrous that a young gentleman from Oxford or Cambridge should, as a matter of course, be received into the Fellowship, while all those holding other degrees should be denied that honour. It is admitted, indeed, that some of the Licentiates may be deserving men, — “ *Quandoquidem fieri potest ut inter Permissos numerentur viri quidam egregii, et de re medicâ præclarè meriti, quos statutum nostrum de Sociis in ordinem Sociorum cooptari vetat,*” — and consequently, by the shewing of the College itself, their exclusion may be a possible injustice. We do not, however, mean that all ought at once to occupy precisely the same position ; but that some mode very different from the present ought to be adopted, of assigning their places to aspirants : that the designations given to them ought to be changed, and that of Licentiate altogether abolished. Nor can it well be regarded as

an unreasonable demand, that they who submit to the ordeal of the College, and pay so considerable a sum as the Licentiates do, should be acknowledged as integral parts of the institution, and admitted to some share in the management ; were it only so far as relates to the election of others into the governing body. As to the manner in which the doors of the College are shut against the newly *admitted* physician, the moment he has paid 56*l.* 17*s.*, it is altogether indefensible. We perceive that it is stated by the petitioners as a grievance that they are excluded from the library and museum. The loss they sustain, indeed, by exclusion from the former, is more nominal than real, — the funds being too scanty to admit of keeping up the collection of books. But here, again, is proof of one of the imperfections of the present system, which would at once be obviated by the income which a few pounds a year from each Licentiate would supply — a contribution which, we are assured, they would most readily make. Would the Fellows rather have a bad library to themselves, than enjoy the luxury and the benefit of a good one, in common with the Licentiates ? We pause for a reply.

These, however, are but minor points, relating to the two orders into which physicians are divided, rather than to the interests of the public. It is this last consideration which, it is to be presumed, will influence our legislators in any change that may be effected. And who will say that the College of Physicians exercise all that control, morally or legally, which ought to attach to the head of such a profession ? The physician who takes out their license gains no honour by it ; he who declines to do so sustains no loss. The unblushing empiric flourishes in their despite ; and the member of their body who chooses to brave the opinion of his bre-

thren, may deal in nostrums and secret remedies, and follow all the devices of the veriest quack, without the College interfering. It is above them or beneath them to gainsay such doings, and in either case the result is the same—they are neutral, negative, and useless.

But it is quite notorious that we and others might write our fingers to the bone without producing any practical effect; for a majority of the Fellows think that the College has hitherto answered their purpose very well, and that it will last their time. With this comfortable assurance, they sit down in the determination to do nothing, except outvote their more active neighbours. The Petition of the Physicians practising in London, however, will probably rouse them from their apathy; and as we know that there exists in the College a considerable number of liberal men, who are sincerely anxious to do what is right, both by the public and the profession, so we are not altogether without hope that the reform may even yet come from within. The approaching recess affords one more opportunity, which, for the sake of all parties, we earnestly hope will not be neglected: if it be so, we are convinced, both from what is passing around and from private sources of information, that another year will not elapse without the appointment of a parliamentary committee or a royal commission,—by neither of which will they be handled as gently as they might even yet be by themselves. But, on the other hand, if the time be turned to due account, and any disposition evinced to the adoption of liberal measures, we doubt not that they will find those who have signed the following petition—remarkable as it is for its freedom from invective—as well as all other well-educated physicians, willing and anxious to co-operate with them in maintaining the respect due to their order, and in raising the character of their College.

We understand that some of those whose names are appended to the petition have formed themselves into an association, with a view of furthering the attainment of their object.

The following petition has been presented to both Houses of Parliament:—

THE PETITION

OF THE UNDERSIGNED PHYSICIANS, PRACTISING IN LONDON,

Humbly sheweth,

THAT the Charter of the Royal College of Physicians of London was granted by Henry the Eighth, for the advancement of Medical Science and for the protection of the public “against the temerity of wicked men, and the practice of the ignorant.”

That six physicians were named in the Charter, who, together with all men of the same Faculty then resident in London, were constituted one body, commonalty, or perpetual College.

That the perpetuity of the College was to be kept up by the future admission of all men of the same Faculty into the College.

That several of the six physicians named in the Charter, studied at, and possessed degrees from, foreign Universities; and that no distinction is mentioned, as regards the University where a physician may have obtained his degree.

That all physicians entitled to practise in London, are equally entitled, under the Charter, to admission to the Fellowship of the College.

Your petitioners are prepared to show, that bye-laws have been framed, and long acted upon, by the College, which are directly opposed to, and in violation of, the letter and meaning of the said Charter.

That the physicians practising in London are invidiously divided, by the bye-laws of the College, into two orders: one is denominated Fellows; the other, constituting by far the majority, is designated (and by implication degraded) by the term Licentiates.

That the Fellows have usurped all the corporate power, offices, privileges, and emoluments, attached to the College; that the Licentiates do not participate in these benefits, but are illegally excluded from all the offices, and any share in the

management of the Corporation; and so far is this principle of exclusion carried, that the Licentiates are not even admitted to the library or museum of the College.

That there exists no foundation in the Charter, or in the Acts confirming it, for such distinction of orders, and consequent exclusion from all privileges.

That, according to one of the bye-laws, no physician can claim admission as a Fellow, unless he has graduated, or been admitted *ad eundem*, at the Universities of Oxford or Cambridge, where medicine is imperfectly taught; while physicians who have graduated at other British or Foreign Universities, celebrated as schools of medicine, are unjustly excluded from the Fellowship by this obnoxious bye-law.

That the College was admonished from the Bench, by the Lord Chief Justice Mansfield, to amend their bye-laws in reference to the admission of Licentiates into the Fellowship; that, influenced by this censure, the College framed other bye-laws, deceptive in their character, which, whenever they have been acted upon, have tended still further to depress and injure the order of Licentiates.

That the College demand and receive a large sum of money from the Fellows and Licentiates, for the supposed privilege of practising as physicians within a circuit of seven miles round London, and that they do not and cannot protect them in this privilege.

That the Graduates of Oxford and Cambridge are obliged to be members of the established Church of England, and, consequently, all dissenters are excluded from claiming the Fellowship; this your petitioners consider as a grievous injustice, and an act of intolerance unbecoming the present age.

That these invidious bye-laws, made in the spirit of corporate monopoly, have involved the College in continued litigation, and created a jealousy between the Fellows and Licentiates discreditable to the members of a liberal profession.

That your petitioners, with deference, submit, that the College of Physicians, as at present constituted, is wholly inadequate to the due regulation of the medical profession in this country, and the protection of the public;—and further, that the Charter of the College in no way provides for the practice of phy-

sicians in the several counties of England and Wales.

Confiding in the wisdom of Parliament, your petitioners therefore pray, that your Honourable House will institute such inquiry into the state of the medical profession in this country, and the College of Physicians in particular, as will lead to the framing of laws, by which the evils complained of may be removed.

And your petitioners will ever pray, &c.

CHOLERA—GOVERNMENT ARRANGEMENTS.

CHOLERA, in the same form as that which excited so much attention about this time last year, is now prevalent in London to a very considerable extent. Influenced probably by the little apparent benefit which formerly resulted from their exertions, the Government had evidently determined to turn a deaf ear upon the rumours which have been for some time afloat on the subject; but this intention seems likely to be defeated by the steps taken by some of the foreign authorities. Sweden, finding that cholera was said to prevail in some of our sea-ports, but without any official admission of the fact being made, has adopted the summary course of placing all vessels from any part of England under quarantine; and France has or-

dered, that ships from London be visited by a health officer before any one is allowed to land. The latter government, we know, has employed an agent in London, to obtain and transmit to them the requisite information on the subject. It is probable that these are the considerations which have within the last few days led to the adoption of measures at home by which the Government shall be enabled to procure statistical returns indicative of the state of the disease in the metropolis. These, we are informed, are to consist in the appointment of medical men in different districts, to report daily the number of cases which occur in their respective departments.

JACKSONIAN PRIZES.

Two prize subjects are proposed by the College of Surgeons, for 1834—viz. 1. Injuries and Diseases of the Nose and Nasal Sinuses; and, 2 Tetanus.

The prize subject for the present year is, The Formation, Constituents, and Extraction of Urinary Calculi. The dissertations to be given in before Christmas: conditions the same as heretofore.

A COPY

of the REGULATIONS or BYE-LAWS under which the Graduates in Physic have been admitted as Fellows of the Royal College of Physicians of London, since the year 1771.

DE ORDINE CANDIDATORUM.

I.—Nemo in Candidatorum ordinem admittatur qui non in omnia Britanniarum Jura natus est, vel qui munus Collegii quodvis exequi per statuta Regni prohibitus est.

II.—Nemo in Candidatorum ordinem admittatur qui non annum ætatis suæ vicessimum sextum clausurit.

III.—Nemo in Candidatorum ordinem admittatur nisi qui in Academiâ vel Oxoniensi vel Cantabrigiensi Medicinæ Doctor creatus fuerit, idque postquam omnia in Statutis utriusvis Academiæ præscripta compleverit, sine dispensatione vel gratiâ insolitâ. Si quis verò Doctoratus gradum in Academiâ Dublinensi adeptus fuerit, volumus ut antequam eligendus pro onatur, literas testimoniales tam ab illâ Academiâ, de præstitis omnibus exercitiis ibi necessariis sine dispensatione vel gratiâ insolitâ, quam ab alterutrâ Academicarum prædictarum de corporatione suâ Registrario proferat. Illos vero qui in prædictis Academicis vel honoris causâ, vel ex mandato quâcunque aut privilegio extraordinario, Medicinæ Doctores creati fuerint,

gradus istiusmodi virtute in Candidatorum ordinem cooptari nolumus*.

DE SOCIIS.

I.—Nemo in Sociorum ordinem admittatur, qui non fuerit aut annum integrum Candidatus postquam Doctoris Medicinæ gradum suscepit; secundum formam de Candidatis dictam, aut è Permissorum numero electus, ut postea statutum est.

II.—Nemo in Sociorum ordinem admittatur, qui non in omnia Britanniarum Jura natus est, vel qui munus Collegii quodvis exequi per Statuta Regni prohibitus est.

III.—Nullus Candidatus in Sociorum ordinem admittatur, nisi prius Præidentem gratiâ impetrandæ ergo visitaverit.

IV.—Nemo in Sociorum ordinem admittatur, qui medicamentum quodvis arcanum, (nostrum vulgò dictum) in morbis curandis ad quæstum usurpaverit, aut qui Pharmacopolæ aut Obstetricis arte aut mercibus quibusvis vendendis victum quærivaverit, nisi gravi aliquâ de causâ Comitibus Majoribus approbandâ aliter visum fuerit.

V.—Nemo in Sociorum ordinem electus admittatur, nisi prius fidem infra scriptam Præsidenti aut Propræsidenti, coram Sociis præsentibus in Majoribus Comitibus dederit:—“Adniteris pro viribus ut status Collegii perpetuetur, statuta Collegii observabis, aut multas tibi contra facienti irrogandas prompte persolves.

“Secreta Collegii foras non vulgabis.

“Neminem aut in Sociorum aut Candidatorum ordinem cooptandum aut ad medicinæ facultatem in urbe Londino et per septem milliaria in circuitu ejusdem exercendam admittendum, decernes, quem, seposito omni affectu, scientiâ aut moribus minùs idoneum esse judicaveris.

“Omnia deniquè in arte medicâ pro viribus facies ad honorem Collegii et reipublicæ utilitatem.”

VI.—Quam fidem literis mandatam quilibet Sociis postquam admissus fuerit, insuper confirmet nomine suo subscripto.

DE PERMISSORUM ELECTIONE EXTRAORDINARIA IN SOCIOS.

I.—Quandoquidem fieri potest ut inter Permissos numerentur viri quidam egregii, et de re medicâ præclare meriti, quos statutum nostrum de Sociis in ordinem Sociorum cooptari vetat; statuimus et ordinamus ut non obstante statuto de Sociis, liceat Præsidenti quotannis nec sæpius in Comitibus Minoribus Ordinariis mense Martis habitis, nisi gravi aliquâ de causâ Comitibus Majoribus approbandâ alio mense vi-

* We omit some regulations regarding secret remedies, which are repeated in the article *de Sociis*. We also omit the forms of examination and of admission, because they are already well known.—E. G.

sum fuerit; unum, pro suo arbitrio, e Permissis qui decennium compleverit à tempore admissionis, utpote morum integritate, doctrinâ et artis medicæ peritiâ insignem, in Socium approbandum Censoribus proponere; qui si Præsident et Censores aut eorum major pars, suffragiis per pilas occultè acceptis consenserit, in Comitiiis Majoribus Ordinariis postridiè nativitatis Divi Johannis Baptistæ habitis, à Præsidente in Socium eligendus proponatur; et si major pars Sociorum præsentium suffragiis per pilas occultè acceptis, consenserit, in Societatem nostram quam primum admittatur.

II.—Non licebit Præsidenti alterum iisdem Comitiiis Minoribus approbandum proponere, sive vir propositus approbatus fuerit, sive rejectus.

III.—Quicumque itâ è Permissorum numero in ordinem Sociorum approbandus proponatur, cum approbandum proponat Præsident in Comitiiis Minoribus hisce verbis:—"Commendo vobis A. B. qui decennium complevit ex quo tempore in Permissorum numerum admissus est; quem, propter egregiam morum probitatem, doctrinam, et singularem in arte medicâ peritiâ, omnino dignum censeo, qui, suffragiis vestris prius approbatus, eligendus in Socium proponatur Comitiiis Majoribus Ordinariis postridiè nativitatis Divi Johannis Baptistæ habitis." Et in Comitiiis Majoribus his verbis:—"Propono vobis A. B. propter egregiam morum probitatem, doctrinam, et singularem in arte medicâ peritiâ, et in ordinem Sociorum eligendum."

IV.—Non licebit Propræsidenti vel Præsidentis vicario hoc officio fungi.

V.—Liceat porro cuilibet Sociorum in Comitiiis Majoribus Ordinariis, postridiè Divi Michaelis habitis, aliquem qui annos septem integros in numero Permissorum fuerit, annumque ætatis suæ tricesimum sextum clauserit, examinandum proponere.

VI.—Nemo verò aliquem è Permissorum numero itâ examinandum proponat, nisi prius in Comitiiis Majoribus postridiè Divi Johannis Baptistæ proximè habitis suum consilium Collegio palam exposuerit.

VII.—Qui Permissum aliquem examinandum proponit his utatur verbis:—"Liceat mihi proponere Præsidenti et Collegio virum egregium, A. B. qui annum ætatis tricesimum sextum clausit, et qui ultra annos septem Medicinæ facultatem exerevit, ex quo tempore in Permissorum numerum admissus fuit; et quem scio esse aptum hilem et idoneum tam Moribus quam Doctrinâ, qui in Societatem nostram eligatur."

VIII.—Is adeo, si consenserit major pars Sociorum in illis Comitiiis præsentium, juxta formam pro Candidatis usitatam à Præsidente vel Propræsidente et Sociis in

tribus Comitiiis Majoribus Ordinariis examinetur; et si in singulis examinationibus à majore parte Sociorum præsentium in illis Comitiiis approbatus fuerit, suffragiis per pilas occultè acceptis Comitiiis Majoribus Ordinariis proximè insequentibus, à Præsidente vel Propræsidente proponatur in ordinem Sociorum admittendus; et si consenserit major pars Sociorum in illis Comitiiis præsentium, suffragiis per pilas occultè acceptis quam primum commodè fieri potest, admittatur, dummodo nec lex terræ nec ullum statutum Collegii nostri eundem ad illud beneficium accipiendum inhabilem reddiderit.

[We are compelled, from want of room, to omit the statement of the finances, but we may observe, meantime, that it clearly proves that no blame can be attached to the College on that score.—E. G.]

ST. GEORGE'S HOSPITAL.

Clinical Remarks on a rare form of Disease of the Knee-joint.

BY MR. CÆSAR HAWKINS.

MR. HAWKINS began by saying that he wished to direct the attention of the gentlemen present to a case now in the hospital, which he imagined was an example of an unusual affection of the knee-joint, (of which, at least, he only recollected having seen four other cases,) and which was well deserving of their examination, since two of those four died; and although in many respects resembling inflammation of the synovial membrane, it was, in fact, essentially different, and did not yield to the ordinary remedies employed in synovial inflammation.

It is the case (Mr. Hawkins said) of William Everitt, 20 years of age, who was admitted on the first of the present month (July). He stated, that on the morning of his admission, while following his employment as a groom, he first felt pain in his left knee, which rapidly increased, so that in *two hours* the joint was so painful and swollen that he could work no longer. When he was brought here, his extremities were covered with urticaria febrilis, and he suffered so much from fever that the house-surgeon placed him under the physician's care, and I have not seen him till the day before yesterday. I need hardly observe, that this acute urticaria is only an accidental coincidence, and has nothing to do with the disease of the knee. The joint, I understand, was at that time very much swollen, and so painful that he could scarcely bear the skin even to be

touched. He attributed the attack to a kick he received a month previously from a horse, but this gave him no pain or inconvenience; and the appearance of the knee is so exactly the same as in the other cases which I have seen, that I have no doubt the kick was not the cause of the disease: in fact, all our patients are fond of attributing any local affection to some previous local injury.

Now, to explain to you what I believe the case to have originated in, let me mention to you the previous cases which I have seen.

The first was a young woman, 22 years of age, who was admitted on the 26th July, 1827, under the care of Mr. Brodie, with considerable enlargement of the knee-joint, and exquisite pain occasioned by the slightest pressure, and with severe symptomatic fever. The pain and swelling had appeared suddenly the day before, without any previous shivering or any injury. Neither had she been particularly exposed to cold or wet, but she had for a month or more been subject to attacks of rheumatism in the elbow and shoulders, and had been leading a life of prostitution. The symptoms and appearance of the joint were not precisely those of rheumatism of the synovial membrane, but they struck Mr. Brodie, whose patient she was, and all of us who saw it, as something unusual, and the case was watched with great interest. On the 28th she was put under the influence of calomel and opium, with much relief; but she continued to suffer from ulceration of the cartilages of the knee, for which blisters and issues were used, but without much benefit, till October 16th, when she was suddenly seized with a severe rigor, which lasted for an hour, and was followed by profuse perspiration. She had severe purging and vomiting, and repeated shiverings. The next day her extremities became cold, and she died in the evening of the 17th. Such are the notes of the Museum book, and here is a preparation of the joint and a drawing of it, which was taken at the time. On examination of the body, some slight peritonitis was found, to which the fatal symptoms were no doubt owing; since, on cutting into the knee joint, not a particle of purulent matter was found, and the knee-joint seemed much reduced in size. The cartilages, however, of the femur (particularly the inner one), of the head of the tibia, and of the patella, were ulcerated extensively, and some blood was effused into the joint, doubtless from the ulcerated surfaces. The periosteum of the femur peeled off more easily than natural, and the bone itself appeared more muscular than usual.

By one of those coincidences which are

so often observed with rare occurrences, another case of the same kind was admitted soon after this, under the care of Mr. Keate, which came on in the same manner, and presented nearly the same appearances; and, after much suffering, this patient also died. On examination of the joint, the cartilages were extensively ulcerated, but there was no purulent matter in the joint, although a good deal of matter was found nearly the whole length of the thigh among the muscles near the bone. The periosteum of the femur was much thickened and condensed, for some distance above the knee, and the bone was vascular, as in the former case.

The third case was that of a patient of Mr. Rose's, soon after the others, which got well, though the ulceration of the cartilages caused, I understand, permanent ankylosis of the joint; but I am not acquainted with all the details of the case.

The fourth was a young woman, 25 years of age, who was admitted into the hospital, under my own care, May 12th, 1830. My notes are these:—She said she had been suddenly seized, a fortnight before her admission, with acute pain and swelling of the right knee, which has been cupped and leeches without benefit. The last two days she has had repeated rigors. Her countenance is flushed, and there is an expression of great distress and anxiety. The tongue is dry, and a little brown in the centre; the pulse very rapid and weak; and she is restless and sleepless to a great degree. There are occasional catches in the limb. The synovial membrane is swelled with fluid, but the cellular membrane around, for some extent, is œdematous, and crepitates in some places. The tenderness is exquisitely great, and she cannot bear the least pressure or motion. At first leeches were used, the joint being much too tender to bear cupping, and colchicum was given in considerable quantity, by which the fever was slightly lessened, but there was not the least improvement in the state of the knee. She was then ordered a grain of calomel, two of antimonial power, and a third of a grain of opium, every six hours; the effect of which was immediate. The very next day, the report says there was less pain and less swelling; and when she had taken this medicine for rather more than a week, the notes say, the pain and swelling have very much subsided, and the patella can be freely moved and pressure made on the synovial membrane without pain. There is now no fever, and there was last night, for the first time, no starting. Pressure of the tibia upwards, however, or of the patella against the femur, gives much pain. In short there remained ulceration of the cartilage of the knee-joint. Some blisters

were then used, and afterwards an issue was made on the side of the joint; under which the disease was finally cured, and the patient left the hospital with tolerable motion of the joint.

Now these cases will shew us, I think, in what respects the disease differs from synovial inflammation; it is in the circumstance of there being acute inflammation of the periosteum of the femur, which is probably the commencement of the disorder, and the affection of the joint ending in ulceration of the cartilages secondary to this, or at all events the concurrence of the periostitis renders the case materially different to one of ordinary ulceration of the cartilages, as well as to one of synovial inflammation. In both the fatal cases, the alteration in the periosteum was evident after death, in one with suppuration, in the other not; and if you examine the joint in the case now in the house, you will perceive the enlargement and thickening of the periosteum for about one third of the femur, with great pain above the joint when the bone is pressed upon. It is evident, also, that the disease is of a rheumatic character, for in all of the patients, rheumatism was present in other joints. In Mr. Keate's case, the inflammation seemed to have attacked the knee first slightly, then rheumatism appeared elsewhere, before the peculiar and fatal inflammation of the femur and knee-joint finally settled in those parts. In my own patient, a somewhat acute attack of rheumatic inflammation came on in both upper extremities after the disease was almost cured in the knee, but then it was of the ordinary character of synovial inflammation; the bones were not affected, and it yielded readily to colchicum, which had no effect whatever upon the disease of the knee previously.

This, then, being my opinion of the nature of the disease, let us now see how you are to distinguish the kind of disease when you meet with it. The disease, you will observe, comes on very suddenly, and in our present patient, two hours produced great swelling and most acute pain and fever: ordinary rheumatism is, however, sometimes very sudden and acute, though the swelling is not often so immediate as in these cases: so that it is chiefly in the local signs that you will recognize the peculiarity of the cases. The pain and tenderness I have already mentioned are found in the bone above the joint as well as in the joint itself, and both are most severe, so as in a short time to cause an expression of great suffering in the patient's countenance, with a tendency to the dry and brown tongue and weak pulse of typhoid fever; though of course this circumstance differs in different individuals.

Neither will you observe them in the present case, as the severity of the disease is a good deal mitigated. You will still, however, perceive something of the peculiar kind of pain which is present: the patient cannot bear the least jar or motion of any kind, either of the foot or any part of the limb. The tenderness is very great even in the skin: Mr. Hick's description of what he observed when this patient first came here is quite accurate; that the skin seemed quite as tender as in an hysterical girl; that is to say, not merely does pressure of the synovial membrane or of the periosteum cause pain, but the least touch of the skin, which can scarcely have reached the diseased parts at all, is also attended with much pain. You may still see a difference in the form of the swelling in the parts; there is not merely swelling of the synovial membrane, but this is in a great measure concealed by an effusion of lymph and serum into the cellular texture, rendering the enlargement more diffused than in common disease of the synovial membrane or cartilages, extending for some way above and below the joint, and having a puffy elastic feeling, with a little oedema in some places; and in my former patient, a distinct crackling sensation was perceived, from the deposition in the cells of the cellular texture. You will observe, too, in Everett's knee, a very peculiar, glossy, white appearance, which you do not see in the more common affections, in which either the colour is unaffected, or if the person is not fat, the skin partaking of the inflammation of the synovial membrane, is actually somewhat redder than usual: in this affection, on the other hand, the skin seems to contain even less blood than usual, so as to produce this almost marble whiteness. Then, again, you have at a very early period, sooner than in common ulceration of the cartilages, and sooner than in ordinary rheumatic inflammation of the synovial membrane, that twitching and starting of the limb, that defined and gnawing pain, and that acute pain on pressing the cartilages of the bones against each other, which indicate ulceration of the cartilages. This arises partly, perhaps, from the acuteness of the ulceration, and partly from the extent of surface which is ulcerated, which you can see in the drawing and preparation is very considerable; while, if common rheumatism affects the cartilages of a joint, it is commonly milder in its progress, the symptoms are more readily mitigated, and the disease more easily cured. The last peculiarity I need specify is the urgency of the constitutional symptoms, the most severe febrile state being almost immediately established. The fever is at first inflammatory, but there is very soon a tendency to the brown tongue

and weak pulse of typhoid fever, passing off at last into hectic, when the state of ulceration and the formation of abscesses bring the joint into the condition in which it is found in ulceration of the cartilages generally. It is then during the first invasion of the fever that it strikes you as unusually severe; there are, even at this time, frequent and severe rigors, with copious perspiration; it seems as if a foul and sloughy abscess was forming, though the examination of Mr. Brodie's case, and the cure of Mr. Rose's and my own, shew that these symptoms may be unaccompanied with any suppuration.

Now then as to the treatment of these cases. The disease resembles synovial rheumatism; but you will see the necessity of distinguishing it from inflammation of this membrane, since the remedies which will cure nearly nineteen out of twenty cases of synovial inflammation, have no power over this case, or if they do check it, the disease yields to them very slowly and imperfectly. I have told you that this disease, perhaps, originates in, or at least is accompanied by acute inflammation of the periosteum of the femur: you know that the only remedy on which you can rely for subduing acute periostitis is mercury, when you are able to exhibit it. Again, the disease is rheumatic, but it is rheumatism of the *fibrous* texture of the periosteum, and not merely of the synovial membrane of the joint: you know, again, that this form, fibrous rheumatism, as it is called, yields commonly more readily to calomel and opium, than it does to those means which are sufficient for synovial rheumatism.

I strongly recommend you, therefore, in the next case you meet with, to employ calomel and opium almost directly in the disease, so as moderately to affect the gums, giving one or two grains, with a quarter or half a grain of opium, every six hours, and continuing it in more moderate quantities for some little time after the severity of the symptoms is subdued. Combining this with some antimony, as in my case, you can begin the employment of it even when the fever is considerable. It was to calomel and opium that Mr. Rose's patient owed her recovery. Mr. Brodie's was also much relieved, though she ultimately died. In my own case, which I have detailed to you, it acted like a charm. After repeated leeching and colchicum had been employed without the least mitigation of her suffering, the very next day after these medicines were left off, and calomel and opium were used, there was a decided improvement, and in less than a week all danger was over of her sinking under it. As I did not see the present patient till a day or two since, I cannot compare his present condi-

tion with that in which he was when he first came to the hospital. I understand, however, that he has, after the first few days, been gradually though slowly improving; but still the disease is by no means cured, and the antiphlogistic plan has been completely tried in his case, as he has been bled in the first instance for his urticaria, and has had nearly 100 leeches used, with colchicum, &c.; and this treatment was commenced the very same day that the disease began. Calomel and opium have been commenced by Dr. Wilson, and under this, I think, we shall witness a more rapid amendment than under the previous treatment. The account which has been given me of what has been done for him is this:—

July 1st.—V.S. ad ξ xv. Calomel gr. v. h.s.s. Haust. Sennæ eras mane.

R. Haust. Salin. c. Magn. Carb. 3ss. 6tis horis.

2d.—Knee more swelled; pain more violent; eruption better.

Rep. Pil. Cal. et H. Sennæ. Hirud. xvij. Lotio. Spirit.

3d.—Urticaria gone; knee very much enlarged, and the pain very great; rigors continued. Still there is a trifling improvement in his general state.

Rep. Hirud. Rep. Haust. c. add. Vini Colch. \mathfrak{m} xx. sing. dosi. Pulv. Ipec. Comp. gr. x. h.s.s.

5th.—Empl. Lyttæ Lateri.

6th.—Hirud. xij. Cont. Haust.

8th.—Hirud. x.

10th.—Empl. Lyttæ Femori.

12th.—Hirud. xij. Cont. Haust. c. Vini Colch. \mathfrak{m} xxx. sing. dosi.

14th.—Pil. Sapon. c. Opio gr. v. o.n.s.

19th.—Hirud. xvij. Omit. Haust. Appl. Fetus et Catapl.

R. Calom. gr. iss.; Opii gr. ss. M. 6tis horis.

On the 24th I saw him for the first time, when the symptoms were still sufficiently marked for you to recognise them, and to observe the several peculiarities which I have pointed out to your notice.

Of course, while I recommend more especially the calomel and opium, which Everitt is now taking, I do not mean that you are not to use leeches, and cold lotion, and similar local means, but that you should trust most to the use of the mercury in subduing the violence of the disorder.

But now comes a second indication in the treatment. The severe inflammation of the bone has subsided, we will suppose, but there remains a serious disease of the joint. The starting and muscular twitches, the severe pain at night in the joint, the

pain on pressing the articular surfaces together, still continue, although the fever and general pain of the limb, with the swelling, and puffiness, and glossy white appearance of the joint, and the tenderness of the femur, have gone off; that is to say, there remains ulceration of the cartilages of the joint, over which, you are aware, counter-irritants alone have real power. You must then, in this second stage of the disease, keep the joint perfectly at rest, and employ blisters and issues till these symptoms are gone. In the ulceration of the cartilages which follows synovial inflammation, blisters alone are usually sufficient; but the ulceration in the present form of disease is more rapid, and you may see from the specimens that it is extensive; so that probably an issue on one or both sides of the joint will generally be required. My former patient had ulceration apparently between the patella and the surface of the femur, and also between the inner condyle of this bone and the tibia; and while several blisters occasioned no diminution of the pain, an issue on the inside of the joint was sufficient to conquer it, and she left the hospital I believe with a useful limb, the motion of the joint having been preserved. In Mr. Rose's patient, on the other hand, although the disease was conquered, I understand that the joint became immoveable after she left the hospital, in consequence of ankylosis.

You may expect me, perhaps, to say something relative to the future progress of Everitt's case; but, in truth, I scarcely feel certain of the state the parts are now in. It is clear, I think, that some ulceration is going on, both where the tibia and femur are in contact, especially on the inside, and also where the patella touches the femur. It is evident also that there is still a good deal of inflammation in the lower part of the femur, which you can feel enlarged and tender (or rather the periosteum is so), for some inches above the joint. But from the degree and kind of swelling which still remains, it is by no means certain, I am afraid, that suppuration may not take place, if it has not done so already, as it did in Mr. Keate's case. If so, the result is of course very doubtful, and he will have a great deal to go through, even if he recovers at all; otherwise we shall have to look to the time when the present line of treatment can be left off, and the disease becomes sufficiently confined to be treated as ulceration of the cartilages alone by an issue. At all events, the case well deserves your watching it to its termination*.

* Since the lecture was given, the patient has improved a good deal, having continued the calomel and opium.—Aug. 6.

CYCLOPÆDIA OF ANATOMY AND PHYSIOLOGY.

WE have received the prospectus of a work bearing this title, and which is to comprise Comparative and Morbid Anatomy, and Pathology, to be edited by Dr. R. B. Todd and Dr. Grant. Such a work, we know, and have often felt, to be a *desideratum*; and if it be only executed in a compendious form, as it is promised, will, we have no doubt, be very acceptable to a large body in the profession. From the names of the contributors, who have engaged to lend their assistance, we should anticipate a high degree of excellence for the *Cyclopædia of Anatomy*: Drs. Bostock, Craigie, Marshall Hall, the Edwardses of Paris, &c. are mentioned among the number. We shall be anxious to hear of the actual commencement of the publication.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE STOMACH AND
BOWELS.

—
DISORDERS OF THE DIGESTIVE
ORGANS.

Causes.—Now the causes of all these symptoms, and of all this derangement, may be beyond the stomach or intestines, they themselves being disposed to be perfectly healthy; or again, the causes may be in those very organs.

Causes independent of the stomach and intestines.—In the first place the causes may be in the groin. A hernia will produce all these symptoms. If a person have a rupture, he is sure to be troubled with irregularity of bowels, costiveness, extreme flatulence, perhaps gastrodynia and indigestion; and if the hernia come up, these symptoms may all vanish away. Any sort of pressure may have the same effect. Obstruction or costiveness, without any fault in the bowels themselves—costiveness from persons neglecting to relieve their bowels, or any accidental obstruction whatever, may produce these symptoms. The presence of worms, or any injurious substances which the patient has taken, may give rise to them, the stomach and bowels themselves being disposed to perform their functions properly if these mechanical or accidental circumstances were not forced upon them. Occasionally these symptoms entirely arise from the individual having taken articles of which the stomach can

make nothing—which it cannot manage. These ingesta may be altogether improper for any one to take, or the individual may have some particular idiosyncrasy. Some persons have a stomach which can digest things in general very well, without any inconvenience to them; but there may be some one or two things which the stomach cannot digest, and if these be taken there is dyspepsia, and some intestinal derangement. You can hardly say that such a person is ill, because the circumstance only occurs when they have taken some particular article of food. I once saw a maid-servant who experienced dreadful gastrodynia, the pain running into the back, causing a rapid pulse, extreme agony, and cold sweats, whenever she took any fruit whatever. She could digest hard salt beef, and her general food, but if she took a strawberry or a gooseberry, she was thrown into the state I have described. Of course an excessive quantity of food will have the same effect as improper ingesta. Nature not only intends us to eat certain things, and not others, but she intends us to eat a certain quantity; and therefore, just as a person may have diarrhoea crapulosa, so they may have dyspepsia crapulosa, the stomach not being in fault, but having more given to it than it ought to have. You will recollect that Solomon says, “excess of meats bringeth sickness.”

Imperfect mastication is another circumstance likely to produce disturbance. Nature does not intend lumps of food to go into the stomach; on the contrary, she intends it to be prepared, to pass through a certain process before it enters the great organ of digestion; and therefore imperfect mastication will produce dyspepsia, without any fault in the part itself. Old people when they lose their teeth, or young ones when they cannot chew as before, and cannot live on spoon victuals, are very subject to indigestion.

But independent of a particular quality of food, or a great quantity,—variety,

or a great discordancy of meats, will occasionally produce dyspepsia.

Still speaking of causes unconnected with a fault in the stomach and intestines, we may mention sympathy. These parts are frequently deranged through the state of other organs. In the first place, we may mention the uterus. When the uterus is pregnant, the alimentary canal is often thrown into disorder. Strange longings of appetite, nausea, and vomiting, will sometimes occur in females the very next morning after they are impregnated, and sometimes these will occur at the time they quicken. There is every intensity of this. You will see it continually in diseases of the kidney, and frequently in mesenteric disease. The passions of the mind, you know, have great effect. If a person have ate a good dinner, and has a violent emotion of mind, whether joy or grief, or any other sudden violent emotion, he will most probably have a fit of indigestion. Continued depressing passions have the same effect. Many cases of indigestion that I have seen, have been referrible to an uneven state of mind: they have not depended on the stomach, but some external circumstance has weighed down their spirits, and the stomach has suffered in consequence of it.

Causes dependent on the Stomach and Intestines.—The cause, however, may reside in the alimentary canal itself. In the first place, there may be a real debility of the part; in the next place, there may be an inflammatory state; and thirdly, there may be organic disease.

As to debility, that is sometimes induced by long continued excess in diet and in regimen. Persons who have indulged excessively in eating and drinking all their lives may expect to be subject to dyspepsia—to have their stomach worn out; but this state frequently arises from an original debility of the stomach. There can be no doubt that the stomach may be in fault, like all other parts of the body. You will see this affection run in families, where there has been no excess whatever. You will see the father or the mother and the children labouring under this disease in various degrees, none having committed any fault. Certain portions of the stomach may be feeble, or the muscular fibres may become weak, like muscles in other parts of the body. Some persons will have one muscle weak, and some another.

There may, however, be an inflammatory state, and this may be primary or secondary. It may be induced like any other inflammation, but in most instances it is chronic, and is induced by constant irritation of the stomach. Sometimes it is a mere secondary effect. The stomach has been affected with weakness, till at last it

has fallen into a state of morbid irritability, and then ultimately into a state of inflammation.

Sometimes, however, you have what is far worse—organic disease of the stomach, and then the indigestion, and all the other symptoms which I mentioned, are irremediable. Generally it is the cardia or the pylorus which is affected; but sometimes, you will recollect I stated, there may be an ulcer in the body of the stomach, and this may be either simple or scirrhus. Sometimes there is no ulcer, but the coats become thickened or softened. All those circumstances may occur that I spoke of, when treating of organic diseases of the stomach. You will recollect I mentioned that the softening of the stomach has sometimes come on suddenly—appeared not to have existed above a few weeks, and sometimes not more than a day or two. You will also recollect my mentioning that this softening was sometimes decidedly inflammatory, and sometimes that there was no mark of inflammation at all, the parts being perfectly white.

From a consideration of all the causes producing disorder of the digestive organs, you see that occasionally it is quite independent of the stomach and alimentary canal, and you have only to remove the unfavourable external circumstance, and all goes on right again. Sometimes you will see the causes are of a nature independent of external circumstances, and removable, or if not removable, controllable, in some measure. In other instances, you will see that it is impossible to cure the affection, or even to control it much. The prognosis, therefore, must altogether depend upon what you ascertain to be the cause of the disturbance.

Removal of urgent symptoms.—As to the indications in treating this affection, perhaps I may say the first thing to be done is to alleviate urgent symptoms. Suppose that any thing injurious in its quality or in its quantity is the cause, the shortest way is to give an emetic, and empty the stomach, and it is much the best to give one that does not produce nausea, but an evacuation. The sulphate of zinc is as safe as any thing you can exhibit. The flour of mustard has also been exhibited for the same purpose. But should you find that the patient is of an exceedingly full habit—for instance, a fat, short-necked, puffy, asthmatic alderman, fifty or sixty years of age—before you give an emetic, it might be necessary to take away blood, otherwise the exhibition of an emetic might cause apoplexy. In some cases, it might be proper to premise bleeding, but in every case it is right to follow up the

emetic by purging. Nothing is better than eight or ten grains of calomel, followed up by senna and salts. You thus empty the patient above and below, and he is soon relieved.

If the symptom be gastrodynia, and you cannot find any thing in the stomach that has occasioned it, then you find tincture of opium an excellent remedy. In the continued form of the disease, prussic acid will answer better, but I never saw it succeed when it was given for immediate effect: when you wish that, I think a full dose of opium is best, and laudanum will act rather quicker than solid opium. You will sometimes find it necessary to give a large dose in this state; 20 drops have no effect, and you have to give 40, 50, or 60, and repeat it every half or three-quarters of an hour, as the dose produces none of the specific effects of opium. Occasionally, it is better to give it in simple, plain, hot water, than in a tincture or brandy, because after a violent spasm there is sometimes inflammation. Occasionally, I have seen people labour under inflammation after spasm has been removed, not because they took opium, but a quantity of brandy. Sometimes you must repeat a dose of laudanum, containing 40 or 60 drops, two or three times, before the good effect is produced.

If the patient, however, labouring under this disease were of full habit, you would in that case find it useful to bleed. Sometimes I have seen gastrodynia cease when the bleeding was over. Venesection is often among the best antispasmodics. After a spasm, tenderness may come on, and then bleeding at the arm may be necessary, or the application of leeches; but the affection frequently occurs without any marks of an inflammatory state, and then laudanum is sufficient to remove it. Hot external applications are exceedingly useful: the temperature falls in this state, and it is exceedingly pleasant to the patient to have a hot fomentation, or hot substances of various kinds applied, not merely upon the stomach, but to the back. I need not say that a hot bath, if it can be procured, would be useful. This state is often called the passage of a gall-stone, for no reason whatever but that it comes on suddenly. You are never justified in saying that an individual is passing gall-stones, unless he has passed them before, and they have been really found, because a pain of this description may come on in a moment from eating an article which does not suit that particular individual, or an external circumstance may occasion it, and there is no difference whatever between it and the passage of a gall-stone.

Suppose the urgent symptoms that require to be removed are heartburn, acidity,

a scalding sensation in the stomach rising to the throat, I need not say that magnesia, the carbonate of soda, and things of that description, are the best. They will remedy this state chemically in a moment, without a reference to the disease itself. In the stomach, there is naturally muriatic acid: as soon as food is taken, muriatic acid is formed, and in some persons it is generated in such great abundance that it produces this affection.

If there be very fœtid eructations, from something putrifying in the stomach, and if the patient be overloaded, distended with them, it is best to give an emetic. If there be no reason for giving an emetic, two or three drachms of the common solution of the chlorurets might be given, and common acids also will answer very well.

These, however, are only means to be resorted to when there are symptoms particularly urgent that require removal. We have more to do in order to cure the disease, and we must lay down for the patient a system for the regulation of his habits and employments.

Treatment.—Having spoken of what ought to be done in regard to lessening any very urgent symptoms that may arise in disorders of the digestive organs, particularly in a violent attack of gastrodynia, we will now consider what is to be done for the cure of the disease—what is to be done in the way of a regular plan for the termination or alleviation of the complaint.

In the first place, we must ascertain the cause of the disease; and if it be external to the stomach, we must proceed accordingly. Very frequently this disorder arises in females from the state of the uterus. In pregnancy it is very common for the stomach to fall into such a state of disorder that the patient's life, for the time, is rendered miserable; and occasionally, from the constant vomiting, from the inability to retain any food whatever on the stomach, life has really been brought into danger. In very extreme cases it has been judged right even to induce premature labour, for the purpose of putting a stop to this great disorder. In ordinary cases, however, although we cannot cure the nausea and vomiting, much may generally be done to alleviate them—not by removing the pregnancy of the womb, but by lessening the irritability of the stomach, so as to make it sympathise with the uterus as little as possible. Simple bleeding at the arm has frequently been sufficient for this purpose, and so has the frequent application of leeches to the epigastrium. All those medicines which I shall hereafter mention, when speaking of another head of treatment, as calculated to lessen the morbid irritability of the stomach, will here be proper—such as strychnine, co-

nium, and prussic acid. It is also proper that the patient should take but a small quantity of food at a time. But I will speak more particularly of this presently.

Of course if we can ascertain that the disease proceeds from a hernia (and which is not uncommon), the application of the taxis may be the only means of curing the dyspepsia. If you discover that there are worms, the remedies necessary to destroy them will be proper, and these I will consider hereafter.

Very frequently the stomach is not in fault, but there is a sluggishness of the intestines; and as the cause is situated there, a regular course of purgative medicine will be found absolutely necessary. It is wrong to give strong purgatives; those which regularly open the bowels are best adapted for the purpose. It is astonishing (I believe I alluded to the circumstance before) how long things will remain which are taken into the stomach and intestines, and then give rise to various symptoms. In the *Philadelphia Journal* for 1822, there is an account of a coagulum of milk which was vomited two months after it had been taken. I have myself seen a coagulum of milk like birdlime, which had remained some days, even a week, in the patient's stomach, producing the greatest uneasiness; the stomach not being in fault, but oppressed by this particular substance. I believe I mentioned that Dr. Barlow, of Bath, published a case not long ago, in which sulphate of iron pills were discharged per anum a year after they had been taken. I have seen a piece of salmon vomited by an infant a month after the nurse had been so foolish as to give the child that food. A case is mentioned in a foreign journal similar to that of Dr. Barlow's, where pills were vomited a year after they were taken. An instance is recorded in which a blacksmith's son bolted thirty grapes—he did not chew them, but bolted them—and after three months' frequent vomiting and extreme suffering, he was cured by an active purgative medicine: ten of the grapes came away whole even then. You will find a case mentioned by Bartholini, where a coagulum of milk as large as a man's tongue was discharged after the patient had taken muriatic acid. The same author also mentions a case where a patient had swallowed a swine's tooth. He suffered under hypochondriasis and extreme emaciation for two years; the tooth was then discharged per anum, and the individual perfectly recovered. You therefore see that occasionally you may have disorder of the digestive organs from articles which have been taken and have remained in the stomach and intestines a much longer time than you could imagine. If, in a

case of disorder of the digestive organs, you suspect any thing of this kind, you ought to employ strong remedies: purgatives and injections, of course, are very important. But whether this be the cause of the disease or not, you will find it of the highest importance to keep the bowels regular. Nothing can be worse than to give strong purgatives for this purpose, excepting where there is something considerable to be brought away. In a case of habitual costiveness, strong purgatives are decidedly bad; because, when you have once acted violently on the intestines, according to the laws of nature they must fall into a torpid state—go to sleep; and during this condition of repose the faeces accumulate again, so that you have to give another strong dose to remedy the mischief of the first, and thus the person is always costive or taking strong medicines, and the consequence is, he is at last obliged to take them or fall into a state of dyspepsia. One of the best remedies for this state is a very minute quantity of croton oil—about the twelfth, the sixth, the fourth, or the third of a drop, given regularly with rhubarb or colocynth; and if it should gripe, a small quantity of aromatic oil may be added to it. You may order one, two, or three drops to be made up into pills, and make the patient take one every night. You will soon find that it will produce one copious stool in the morning, and you also find that the medicine may be taken for two or three years, perhaps for ever, without losing its effect: the patient will not be under the necessity of increasing the dose. If, however, you give it violently, the patient will be in the same condition as if he had taken other purgatives—he will be costive afterwards. Nothing can be more absurd than to give blue pill, calomel, and mercurial medicines, because they have a two-fold operation; they not merely act as cathartics, but they pervade the whole system, and thus make the patient weak and nervous. These medicines do more than you want: you merely require the intestines to be acted upon, and not the intestines at large to be put under the specific action of mercury. If Mr. Abernethy had lived a hundred years, and done good all the time, he would not have atoned for the mischief he has done in making people take blue pill. Half the people in England have been led to fancy that they cannot live without blue pill; which does no more good than any other purgative, but renders those who take it constantly susceptible to cold, and altogether must be very injurious.

I may here mention, that there are some persons who have very torpid bowels naturally—to whom it is not natural to have a motion every day. I presume, that

in ninety-nine cases out of a hundred it is natural for the bowels to be emptied once in the twenty-four hours; but there are some who do not have a motion above once in three or four days, and they are ill if they do. I have met with such cases. Dr. Heberden knew a person who, all his life, had but one motion a month: he must have had a great deal to carry about with him;—and then, as a contrast, Dr. Heberden mentions another individual who had twelve motions a day for thirty years: that must have been equally troublesome—it was perpetual motion. This same individual, then, had a motion seven times a day for seven years.

Women are much more costive, and suffer this with more impunity, than men, on account of the pelvis being large and the rectum distending. Nothing is more common than for women to tell you that they have been a week or ten days without a motion. You must therefore take into account that it may be natural to some individuals to have a motion only every few days.

In a case of disorder of the digestive organs, you should always examine into the state of other parts of the body; for this condition will take place, not only from sympathy with the uterus, but with other organs.

A very common cause of this disease is disorder of the brain—what is commonly called disorder of the mind. From anxiety, grief, and distress of mind, many persons have stomach complaints. So far as the stomach itself is concerned, they have no reason to find fault, but through the state of the mind the stomach cannot do its duty. Excessive anxiety, or grief, will not only take away the appetite, but produce a constant imperfection of the functions of the stomach, and all the symptoms of indigestion and derangement of the digestive organs which I formerly mentioned. I have very frequently been unable to do any material good, because the complaint evidently depended upon the state of the mind; and very frequently I have gained credit where I deserved none, simply from the circumstance of the unhappy state of mind ceasing. I have very frequently attended young ladies who could not digest—who had flatulence of the stomach, no appetite or great appetite, every thing that could be wrong—simply because there was an anxiety on love affairs; they were in fear of disappointment; and as soon as the affair was settled they ate, drank, and digested, like other people, without any inconvenience, but on the contrary with great benefit. I have frequently been baffled in what appeared good rational treatment, because

there was some grief of mind or some constant anxiety.

It is always right to look out for any particular habit, to see whether the patient is constantly doing any thing to which you can attribute the disease. Dr. Cullen mentions two cases of dyspepsia from patients taking snuff before dinner. In one of these two cases, the disorder of the stomach was gastrodynia—aching pain of the stomach; and in the other case, there was a complete loss of appetite. Now both these individuals on being particular not to take snuff before dinner, taking as much as they chose when the stomach had something in it, recovered from their dyspepsia; the one lost his gastrodynia entirely, and the other recovered his appetite. With regard to myself and tobacco, if I smoke three cigars in a day, or smoke three or four successive days, I invariably have dyspepsia. Although I have the best stomach in the world, one that will digest any thing in the shape of proper, good, nourishing food, yet if I smoke in that way, it invariably produces the most extreme gastrodynia and cardialgia, so as to make me quite miserable, and therefore I am compelled to be temperate in that respect. You will find that many persons have this disease from going too long without food. Habit has a great deal to do here. Some persons feel no inconvenience who breakfast at nine in the morning, and dine at seven in the evening, taking nothing in the meantime; and others suffer the greatest inconvenience if they fast more than four or five hours. You will find that habit will not operate on some people in regard to this point—that some persons cannot be brought to fast long, and it is in vain for them to attempt it. They feel a sinking in the stomach, they have gastrodynia induced, if they do not eat frequently. Some cannot pass above four hours, and in proportion to the labour undergone, so is the necessity for eating. You should, therefore, in making inquiry into dyspeptic cases, ascertain how frequently the patients eat; but you should also ascertain whether they eat too much, because the stomach must not be blamed if it does not do double or treble the duty that nature intended. It is said, that in the reign of Henry the Sixth, the people ate but twice a day; “whereas,” says Hollinshed, “we have breakfast in the forenoon, breakfast after dinner, and rare suppers when it is time to go to rest. Now these additional repasts are very well left out, and each one should content himself with dinner and supper only.” Another point is to ascertain if the patient chews his food. Many persons gobble up their dinner as an

elephant would do, instead of chewing it properly. Another point is, to ascertain what is the person's diet, and to regulate it for him. You know that some nations live on fish, others on stinking animal matter, and others on vegetables. An eagle has been brought to eat bread, and a pigeon to eat meat, the former being a bird of prey, the latter a domestic bird. John Hunter brought a hawk to live on bread. If these changes be accomplished slowly, they may be well borne; but many cases of indigestion arise from persons suddenly changing their diet. It is mentioned that our countrymen who were prisoners under Tippoo Saib, were fed during their confinement upon nothing but rice, water, and capsicums; and on their return, when they were liberated, they of course ate as before. The effect of the suddenness of the change, even to their former diet of meat, was such, that violent diarrhoea was induced. Very frequently you will find persons suffer in this respect from a change of food, and even from a change of place, from having different bread from what they have been accustomed to, and different water from that which they formerly had.

We see the effect of habit every day around us, because the lower orders will eat such butcher's meat, and such fish, as would disorder the stomach of their superiors, without appearing to suffer from it.

Now, there can be no doubt, that, generally speaking, food is best composed of a mixture of vegetable and animal substances. It appears from the teeth, and it appears likewise from the experiments made with the solvent juice of the stomach, that digestion is most likely to take place with facility, and in perfection, if the diet consist of a portion of animal and vegetable substances. In general, too, the food is much better digested, if a certain degree of art be applied in its preparation—the art of cookery. Some persons, with weak stomachs, require this art in full perfection; they do not digest things unless they are thoroughly boiled—thoroughly pervaded by heat, either dry heat or heat and moisture, and even then they require the addition of good spices.

It is therefore necessary, in regard to patients labouring under this affection, to ascertain whether they have made any change—whether the meat they eat is good of the kind; to ascertain, also, whether they eat a proper proportion of animal and vegetable food; to ascertain that they do not eat things raw, which might be dressed. Many persons, for example, have indigestion only when they eat articles not thoroughly cooked, and some persons digest every thing, except raw vegetables, salad, and radishes.

In general, brown and old flesh is better digested than young meat. Mutton is easier of digestion, for example, than veal, and capon than a young chicken. In general meat that is not particularly fat is better digested than when it is, and lean than fat itself. Fresh meat, too, is usually better digested than salt meat: salt hardens the fibre, makes it more compact, and less easy of solution. Dr. Robinson addicted himself to taking a vomit every evening, and he found that he brought up veal undigested, but when he dined on beef, very little remained; shewing that the latter is of more easy digestion than the former—old flesh than young.

In regard to fat, it is a curious circumstance that some persons who cannot digest a great number of articles well, can digest a piece of broiled bacon thoroughly, and now it is the fashion to take broiled bacon as a thing very easy of digestion. Mr. Cunningham, a surgeon, who wrote an account of New South Wales, states that he knew a person in whom the smallest portion of beef or mutton fat deranged the stomach; and she was forced, before she could take gravy, to allow it to get cold, and then have it skimmed and warmed again, so that not a particle remained in it; and yet she could eat broiled fat bacon with impunity.

Another point to be attended to is, not to take much liquid food into the stomach—not to indulge in broths and slops, which is so much animal matter with water into the bargain. It is better to take animal food in a compact form than in a lot of hot water, because, no doubt, a quantity of liquid is injurious to the stomach: it dilutes the gastric juice, and one must suppose, must relax the stomach—must both sodden it, and diminish its powers. It is wrong to drink too much liquid of any sort, even beer, and tea, were there no other reason than that I have just assigned. One of the best things to drink after dinner is a cup of very strong coffee, without any milk; some persons, however, are so stimulated by this, that they cannot bear it. But, in general, it is a good rule for dyspeptic people to limit the quantity of drink as much as possible; to take no slops or broth; and in preference to drinking beer or water, to take a cup of strong coffee.

In regard to vegetables, waxy potatoes are seldom well digested, and it is necessary that greens should be thoroughly boiled, that is to say, boiled in a large quantity of water, and boiled very vigorously.

You will find many persons much better without beer or wine; but some have a stomach so languid that it requires the stimulus of wine. You cannot prescribe any particular wine. For some persons,

Port is best; for others, Sherry; and for others, again, Madeira. With some people, Port turns acid, and with others Sherry; but in a great number of cases, you find that Sherry agrees with the stomach best. A mixture of wine is bad, and persons will frequently bear Port, Sherry, or Madeira, when they would be made ill by taking any two of them together; but some add beer to a mixture of wines, and then you may expect a treble commotion in the stomach. Some say, that if they take a glass of brandy, that settles all: it is like oil poured on the sea in a swell. But you find many persons' stomachs so susceptible, that no wine can be drank, and indeed nothing but brandy and water can be borne. As to Champagne, Burgundy, and home-made wines, they are sweet, and generally disagree with the stomach: still you will meet with exceptions, and you will find cases where vomiting is stopped by Champagne. All Rhenish wines are sour, and likewise Claret, and these usually ferment in the stomach, become acid, and therefore they are improper. Generally one wine only should be taken, and that which usually answers best is Sherry.

It is well to prevent persons labouring under this complaint from eating suppers, unless they have had an early dinner. If people dine at one or two o'clock, it is necessary for them to take something in the evening. Now and then you will meet with persons who are not so well without a good supper: they will lie awake from irritability brought on by exhaustion, unless they eat suppers, and therefore there is no rule for these things. There are general rules, such as I have now mentioned, but you must never stand up for them universally; you must make exceptions, and adopt what you find the patient's constitution requires.

You will find it very proper to advise some persons to eat brown bread, instead of white: many persons will not be costive if they eat brown bread, but in others it produces a degree of heartburn and acidity.

It is almost always right to advise persons to remain quiet after dinner; if there be much moving about, digestion does not go on so well. It is a common saying,

"After dinner sit awhile,"

and it is also said,

"After supper ride a mile:"

not to digest the supper, but because the person should have eaten so light a supper, that he may ride a mile without doing him any injury.

You thus perceive that much may be done in curing disease of the digestive organs without any medicine at all, simply

by discovering the cause, and removing it, and this cause is very frequently some bad habit. It is absurd, in every case of stomach affection, immediately to order something. You should sit down, learn the history of the case, ascertain if the cause is beyond the stomach, if it has its seat in any other organ, ascertain what is the state of the intestines, what is the condition of the mind, whether the patient has been fasting too long, eating too much, taking something that disagrees with him, and if it arises from any of these causes, you may cure the disease without any medicine—may put the patient in possession of a plan which will put a stop to his ailments. I am quite sure, that in the greater number of cases of indigestion, the disturbance arises from things forced into the stomach, from the state of the mind, or from some injurious habit which the patient has contracted; but it is necessary to attend to all the points I have mentioned with regard to diet, because some persons have such weak stomachs that they require a particular line of conduct. Articles which produce indigestion in some people will not give rise to it in others.

We may perhaps, however, have to treat disease of the stomach itself. Independent of all external circumstances—of things external to the stomach, the stomach itself may be in fault.

Having cleared the way so far, we should look out for inflammation;—ascertain if there be gastritis. If you find a great sensation of heat in the stomach, and up the throat, and if you find the part tender on pressure, you must treat the case as you would any other inflammation. Leeches continually applied to the pit of the stomach, moderate purging, and mild diet, are the suitable means. Supposing we find no such marks of inflammation, but morbid irritability, and the stomach suffers pain when food is taken, although there is no pain on pressure; or suppose the stomach vomits, discharges its contents, and there is no pain or heat, so that we may hence conclude that the case is one of morbid irritability; for the purpose of lessening this, you will find that prussic acid is one of the best remedies. In gastrodynia it answers exceedingly well. If there be inflammation united with this spasmodic pain, you must remedy that by leeches; but if there be merely spasmodic pain, or a constant aching at the stomach, you will find prussic acid frequently answer very well. It is best to begin with one minim three times a day, taking care not to give it on an empty stomach; and for this reason, a dose that will be borne very well when the stomach is full, cannot be borne when it is empty. All agents affect the stomach most when it is empty, when they

come in contact with it, when they are not mixed with its contents, and consequently not diluted and partly applied to the organ. If you give some doses before meals, and others after it, it will not produce an uniformity of effect. It is best to equalize the dose by giving it after meals. You may begin with a minim, and in a day or two increase it to two minims, then to three, and so on. The symptoms which it produces of an unpleasant kind, and which are sufficient to make you limit the dose, are sickness, faintness, convulsions, and a little pain in the head. You must tell the patient of these things, and guard him against the occurrence, desiring him, if they take place, to desist immediately—not to take so large a quantity again, but a smaller dose. Then, as to the dose, there is no rule whatever. I believe I mentioned I had a patient who could not bear more than the fourteenth or seventeenth of a drop without uneasiness; and I had another who said he took seventeen minims three times a day, but he could not reach above that. I have several times seen patients who took eight or nine minims three times a day; and even this is a large quantity. The usual dose that is borne varies from two to four minims, perhaps.

Hyoseyamus, conium, and strychnine, are given for the same purpose; but better than any of these, I think, is stramonium and opium; and I think stramonium is the best, because opium confines the bowels, and that is injurious in these cases. I have seen stramonium cure this pain in the stomach—gastrodynia. There is no rule for the dose of this medicine; but it is well to begin with half a grain, two or three times a day, and gradually increase it while there are no unpleasant effects: these are, pain of the head, convulsions, giddiness; and if the remedy be given incautiously after these begin, you may have drowsiness, violent pain, violent throbbing of the temporal and carotid arteries, and sometimes, perhaps under almost all circumstances, thirst and great dimness of sight. If the two latter symptoms are not considerable, the patient may bear them; but if convulsions, giddiness, and pain of the head, be induced, it is well to omit the remedy immediately, and then give a smaller quantity.

Next to this, conium answers very well; but very frequently it requires to be given in increased doses, up to 10, 15, or 20 grains, three times a day. Opium is also proper in these cases, where a patient's bowels are relaxed, and you are anxious for it to have a double effect. In regard to the feeling of morbid irritability, that is much better put a stop to by prussic acid than by stramonium. I have frequently seen it stopped by the first or second dose;

but the gastrodynia, the aching of the stomach, I think is best relieved by stramonium. Prussic acid answers very well, but I have seen it fail where stramonium cured the case with facility. The sub-nitrate of bismuth has been used to lessen gastrodynia, and no doubt with good effect; the ung. antim. tartarizatum has also been employed. It is well to give in these cases but a small quantity of food at a time: for the stomach, when much distended, falls at length into a spasmodic state. The more distended the stomach is, the greater effort does it make to contract, and the greater is the spasm; and therefore a small quantity of food is proper.

As to the symptoms of morbid irritability of the stomach, you have carefully to remember that it may be united with gastrodynia, and you must remember that the morbid irritability may at different times amount to inflammation; so that the remedies which, in the first place, were calculated to relieve it, will no longer do so, and the remedies for inflammation must be employed. You are never certain, from day to day, whether the symptoms depend upon inflammation or morbid irritability: occasionally you have to apply leeches, and the proper remedies for inflammation; at other times those that I have now mentioned, and frequently you have to employ both; there is a degree of tenderness, but more pain than tenderness, so that both plans are proper. Frequently prussic acid and conium are improper—the remedies for inflammation are required; in other cases the remedies for inflammation are improper—the patient requires narcotics; and, again, you have other cases where both plans are proper.

Then, thirdly, you may have another condition of the stomach, where there is no gastritis, no inflammation, no morbid irritability independent of inflammation, but where the stomach is torpid. You will have some patients with what is called a *cold stomach*: they can digest their food if they take brandy and cayenne pepper. Now in indolence of the stomach, aromatics are generally good—mustard and cayenne pepper; and in regard to medicines, ether, camphor, fortid substances, and ammonia, will be found useful. Dr. Baillie says, that where, in disorder of the stomach, a quantity of viscid mucus is discharged, comp. tinct. of Benzoin is an excellent remedy, but where there is pain on pressure I would not give such a stimulating medicine.

In disorders of the stomach, it would be absurd always to tell patients to abstain from wine, and to take nothing rich; for you find some persons who digest better if they take a few spiced articles and a few

glasses of wine—perhaps a pint. Some must have wine, and even spirits.

In some cases of this description, the application of galvanism to the epigastrium has been found very serviceable. Tonics of various kinds are useful in this weakness and torpidity of the bowels, and especially iron—particularly ferrum ammoniatum, which is one of the most stimulating preparations of iron. Bitters are useful; and to these, people often add soda, which is a good stimulant. Acids, as well as tonics, have been found useful, and they are often the best remedy for acidity: they destroy that state of the stomach which gives rise to it.

Nothing can be worse than for people to vomit and purge themselves in these cases, which they frequently do. These things must weaken the alimentary canal. It is right to enjoy plenty of fresh air—patients ought to avoid confinement; they should have exercise short of fatigue, and have a pleasurable occupation. It should be a constant occupation without care.

ON INFLAMMATION OF THE BLADDER.

BY WILLIAM COULSON,

Surgeon to the General Dispensary.

SURGICAL writers in this country, who have directed their attention to diseases of the bladder, appear to me to lay too little stress on the distinction between the inflammations of the different structures of which the bladder is composed. The French, in their systematic works, mention the acute and chronic vesical catarrh, and acute and chronic cystitis; designating by the former, acute and chronic inflammation of the mucous membrane of the bladder, by the latter term, acute and chronic inflammation of the other tissues of this organ. And here I may observe, that the term acute vesical catarrh cannot correctly be applied to acute inflammation of the mucous membrane of the bladder, because it implies the existence of a symptom, namely, the discharge of mucus, which is not invariably present in this disease. In fact, the whole of the mucous membrane of the bladder may be destroyed, and very little mucus be secreted. No one can be more fully aware than myself of the difficulty which exists in determining with precision the particular structure affected; but as I consider the dis-

tingtion of considerable importance, I have endeavoured, in the following pages, to detail with accuracy the symptoms of each affection: and first of

Acute Inflammation of the Mucous Membrane of the Bladder.

The symptoms of this complaint are, frequent desire to pass the urine, accompanied with darting, shooting, throbbing pains in the region of the bladder, and these are increased by pressure on the part, or any motion of the body. There is a sense of heat or burning along the urethra: the urine is high coloured, and passed in small quantities. Sometimes there is sickness, and uneasiness in the loins, but not invariably. The pulse is quick, and at first full, but afterwards small; the tongue is white; countenance anxious; skin dry; and there is generally great thirst. The urine, on examination, will be found to be very acid, and frequently to contain small flakes of lymph. If the disease be not arrested in the early stage, ulceration of the mucous membrane is likely to occur, and in the worst cases it proceeds till the whole of the mucous membrane is destroyed. The ulcerative process may extend so deep into the substance of the bladder as to cause perforation of its parietes, and cases are recorded of extravasation of urine taking place into the abdomen from this cause*. Sometimes, also, a communication is formed between the sigmoid flexure of the colon and the fundus of the bladder, or between the rectum and the under surface of the bladder; in the former of which cases the feces, I believe, pass into the bladder, and through the urethra; in the latter, the urine goes into the rectum, and is voided per anum. But the more usual course of the disease is, that the ulcerative process gradually extends, till the whole of the membrane is destroyed, and then the muscular structure is shewn better than any dissection can represent it. In the progress of the ulceration, disease usually manifests itself in one of the kidneys: this is indicated, not so much by pain in the loins, which, in the cases I have watched, was not present, but by the sickness and rejection of every thing taken into the stomach. In the advanced stage, large quantities of pus are voided by the urine, and the urine is tinged with blood.

* Baillie's Morbid Anatomy, c. vi. 1793.

Attempts have been made to determine by the qualities of the pus itself, whether it has been secreted from the bladder, or has passed from the kidney into the bladder. In the cases which I have seen, the pus has come from the kidney; I am, therefore, unable to speak on this point from my own observation. Soemmering* says, that the pus from the kidneys mixes more easily with the urine, and is more pure than that from the bladder, which is generally mixed with mucus, and consequently somewhat ropy and sticky. The most certain criterion, however, of the kidney being affected, is the state of the stomach.

If there be a stone in the bladder, all attempts at cure, till the stone be destroyed or removed, will be ineffectual. The severity of the symptoms will depend on the composition and size of the stone, and the constitution of the patient; and if the operation will not be consented to, these circumstances must guide the surgeon in the selection of the palliative remedies which he may employ. If the disease of the bladder co-exist, or be connected with organic mischief in the kidney or any other organ, little or no good will be derived from medical treatment. But as I am speaking of idiopathic inflammation of the mucous membrane of the bladder, I will pass over cases occurring from causes such as those to which I have alluded. Blood should be taken by leeches from the hypogastric region, and these should be repeated as long as the severity of the pain continues, and the strength of the patient will allow. But when the abstraction of blood can no longer be borne, then I advise the tartar-emetic ointment to be rubbed in just above the pubes, every night. Anodyne injections, composed of a third of a pint of thin starch or gruel, with twenty or thirty drops of Battley's sedative solution, should be exhibited at bed-time, and great relief will be experienced from their use. Some recommend the injection of oil and opium, and other substances, into the bladder, by means of a gum-elastic catheter; and in one of my patients this plan had been suggested by an eminent physician, prior to the patient being placed under my care, but no benefit was derived from this treatment. In fact, the pain and

irritation which are experienced from the introduction of instruments into the bladder in these cases, are so considerable as to deter me from employing this plan. The hip-bath at night will be found very serviceable. Animal food, wine, spirits, all fermented liquors, and acid drinks, should be interdicted. The diet should be light, consisting of bland, farinaceous food, and the drink of barley water, toast and water, or linseed tea.

When the surgeon is thoroughly satisfied that no stone exists in the bladder, the introduction of catheters and sounds (unless there be retention of urine, which is not common) should be avoided, because the patient experiences great pain, not only when the point of the instrument comes in contact with the bladder, but also in its passage along the urethra.

When the severity of the pain has been subdued, I have found some benefit from the decoction of *parcira brava*; but I think this medicine more serviceable in the chronic form of the complaint. Hyoseyanus, opium, lime water with syrup of white poppies, may from time to time be administered; but I fear that it is not within the reach of medicine to cure this distressing complaint. It more frequently attacks the young and middle aged than old persons, and females are said to be seldom attacked with the complaint; but I am doubtful of the correctness of this opinion.

Anxiety, cold, too free indulgence in ardent spirits and strong ales, the use of too powerful injections or medicines for the suppression of gonorrhœa, stone, and diseases of the rectum, may produce this affection. Soemmering lays great stress on suppressed gout as one cause of the complaint. In some cases, I have not been able to trace it to any cause.

This disease is very likely to be mistaken for stone: the uneasiness in the bladder, frequent desire to make water, and the passage of blood with the urine, are symptoms of stone as well as of this complaint. But, in stone, the pain is principally experienced after the bladder has been emptied; whereas, in acute inflammation of the mucous membrane of the bladder, the pain is most intense when the bladder is full, and subsides when it is empty: in stone, larger quantities of blood are passed than in this disease, and the urethra is seldom so irritable.

On dissection, the mucous membrane

* Abhandlungen über die schnell und langsam tödtlichen Krankheiten der Harnblase und Harnrohre, p. 36, 1st edit. 1809.

of the bladder will be found to be more or less destroyed, and the muscular structure beneath distinctly shewn. The ureters are inflamed, dilated, and sometimes ulcerated; abscesses form in one or both kidneys, or deposition of a white, chalky matter takes place. In extreme cases, inflammation extends to the muscular structure, which may be either destroyed or present a gangrenous appearance. Mr. Brodie says that coagulated albumen is deposited in the cellular texture by which the bladder is surrounded, and not unfrequently small putrid abscesses are formed in it; and sometimes it is found after death in a state of slough, or approaching to it. The prostate gland is usually enlarged, and the lining membrane of the urethra is highly inflamed. I possess a preparation in which coagulable lymph is diffused on the surface of the urethra in this disease. The first of the following cases illustrates the symptoms, progress, and termination of this complaint. In the second case, the disease of the bladder was, I believe, the secondary affection, and dependent on disease of the kidney.

CASE I.—Inflammation of the Mucous Coat of the Bladder.

I was requested on the 17th of May, 1832, to visit Mrs. M., æt. 36, who was supposed to be labouring under symptoms of stone. She had frequent desire to make water, attended by darting shooting pains in the region of the bladder, which were much increased by walking, or exercise of any kind. The urine itself was acid, and contained some shreds of lymph or mucus. No blood or gravel had been ever passed. I sounded the patient, and the instant the instrument was introduced into the urethra, the pain experienced was most intense, and this continued during the whole of the examination. No stone could be felt. The pulse was small and quick, skin dry and rough, tongue white, countenance anxious, and indicative of much suffering. I expressed from the first a very unfavourable opinion of the case, believing, as I stated, that there was ulceration of the bladder. She had been in this state for two months, and various remedies had been tried. I suggested the use of the pareira brava, first in the form of infusion, then decoction. The uneasiness of her symptoms was certainly relieved more by this medicine than any thing else

which she tried. For the first six weeks leeches were occasionally applied to the hypogastric region, and tartar emetic ointment rubbed in; and at night a thin starch injection, with twenty minims of Battley's sedative solution, was given. After this time Mrs. M. simply tried the decoction of pareira brava till about two months prior to her decease, when perceiving more mucus in the urine than usual, and occasionally blood, I added a very small quantity of balsam of copaiva to the mixture (two drachms to eight ounces of the decoction, with some mucilage.) This brought on sickness, and deranged the stomach so much, that she was obliged from this time to desist taking the decoction. She now had sickness and nausea, pus was voided with the urine, there was complete loss of strength, emaciation of the body, hectic flushes, and on the 24th of November death put an end to her sufferings. It should be observed, that for a few days prior to her death no pus had been voided with the urine, and the pain and frequent desire to make water, for the only time during her long illness, had almost left her.

The body was examined within 48 hours after death by Mr. Merriman, of Kensington, and myself. The bladder was not thickened or contracted, but so completely divested of its mucous membrane, that not a single vestige of this coat could be seen. No dissection could represent the arrangement of the muscular structure so well as it was seen in this case. One spot, of the size of a shilling, towards the fundus, was black, and almost gangrenous. The ulceration had not extended to the urethra, but its lining membrane was highly inflamed. The right kidney was natural, but there was ulceration of the left, and its interior was filled with pus. The renal extremity of the left ureter was blocked up by a detached portion of the substance of the kidney.

CASE II.—Ulceration of the bladder, ureter, and kidney.

Deborah Mulladay, æt. 46, was admitted under my care at the General Dispensary, for an affection of the bladder. She complained of great uneasiness, and sometimes pain, in the lower part of the belly, and frequent desire to void urine; after the bladder was emptied, the pain and uneasiness usually subsided. These symptoms were at

first relieved by the use of the decoction of the *pareira brava*; but after six weeks, they became more aggravated, the pain was at times very acute, the desire to make water more frequent, the urine contained a good deal of pus, and on two or three occasions was tinged with blood. The pulse was small and quick, and the countenance pale and sallow; there was emaciation of the body, with occasional shiverings, and cramps in the leg. She had no pains in the loins, and there was no sickness until about ten days prior to her decease, when it was very distressing, and continued for some days. On Friday, July 26th, she was seized with paralysis, and expired on the following Tuesday.

The body was examined 24 hours after death. The mucous membrane of the bladder was ulcerated in several spots, but was not so much destroyed as in the preceding case; the bladder was thickened and contracted, and contained a good deal of pus. The vesical extremity of the left ureter was ulcerated, the pelvis of the left kidney was full of pus, and the substance of the kidney in some parts completely destroyed by ulceration. The right kidney was in a state of atrophy, and its interior contained a deposition of chalky matter. The urethra was inflamed, but not ulcerated.

CASE III.—*Ulceration of the bladder.*

William David Sadler, aged 17, of a delicate constitution and light complexion, applied at the General Dispensary, December 3d, 1832, for an affection of his bladder. Says that about seven months ago he first felt pain in making water, which lasted for some minutes, and then went away. Since that time this symptom has never left him. All of a sudden he feels a darting pain near the neck of the bladder, accompanied with an irresistible desire to make water. The pain then subsides; he makes water, and still feels easier. These attacks vary as to the frequency of their occurrence—sometimes every hour or oftener, at other times at longer intervals. The urine is turbid, and voided in small quantities, and extremely acid. Appetite good; general health not much deranged; pulse quick; tongue white and dry. A sound was introduced two or three times, but no stone could be felt: this operation always gave him great pain. No blood has ever been passed;

there has been no sickness, nor do any of the neighbouring organs suffer.

Alkalies and hyoseyamus; small doses of eubebæ with carbonate of potash, the decoction of the *pareira brava* alone, and also in combination with small doses of copaivi and mucilage, with hyoseyamus, were tried; but he has been benefited by nothing which he has taken, and he continues now in the same state as when he first applied.

Chronic Inflammation of the Mucous Membrane of the Bladder.

A patient labouring under this disease, first complains of an uneasiness in the region of the bladder, which occasionally extends along the urethra, and at other times is only felt at the glans penis. There is a frequent desire to make water, which is passed with pain and difficulty, but after the urine is voided the pain subsides. The urine is acid, usually contains some mucus; the mucus itself is alkaline, and when passed in large quantities imparts the same character to the urine. The quantity of mucus secreted varies—at first it is small, and sometimes is never much. In other cases, however, it is considerable; and instances are related where several pounds have been passed in the 24 hours. The mucus is thick and viscid, or ropy, and when allowed to remain long in the urinal, it presents a very ammoniacal smell. From the quantity of mucus secreted, the complaint has obtained the name of vesical catarrh. It is sometimes slight in its constitutional effects, and disappears soon; at other times it continues for a considerable time, producing great emaciation, and even death. This disease is more under our control than the acute form, and though it seldom if ever admits of being completely cured, still it may be kept under, and the patient, with care, may suffer but little annoyance from this complaint.

The observations which I made in reference to stone, as a cause of the acute form of the disease, are applicable here; but it is also frequently caused by stricture of the urethra, enlargement of the prostate, prostatic calculi—and our treatment in such cases must be directed to those affections. Where, however, it is an idiopathic affection, medicine will be found to be very serviceable; and of all the medicines which I have tried, the decoction of *pareira brava* has ap-

peared to me to do most good. This medicine formerly had a place in the Pharmacopœia, and was very much in repute in the beginning of the last century. In a work published at Paris, in 1704, by Andreas Helvetius, this author considers it a specific for some inflammatory affections of the bladder*. Where there is a considerable secretion of mucus, I find the decoction of the uva ursi, with the muriated tincture of iron, of great use. This medicine will sometimes lessen the secretion of the mucus, when the pareira brava will not; this latter medicine having a greater influence over the pain and irritability of the bladder than over the secretion of mucus. If there be any tendency to gout in the constitution, the colchicum† should be administered at bed-time, and powdered galls, with nitre, three or four times in the day, to repress the mucous secretion. Small doses of copaiivi, with hyoseyanus, will sometimes do great good in these cases, and may be added to the decoction of the pareira brava, or given alone. Small doses of cubebæ, combined with the carbonate of potash and powdered calumba, are of service. But both cubebæ and copaiivi must be administered with considerable care; for it has fallen to my lot to see more cases of chronic inflammation of the bladder produced by the long-continued use of large doses of these medicines than by any other cause.

As the disease lasts for a considerable period, and patients, from long experience, understand the management of their own cases, the opportunities of dissection are not very frequent. The mucous membrane is sometimes ulcerated; and where it is not destroyed, it is inflamed, and presents here and there red spots, as if blood had been effused beneath its surface. A case of this disease, which was relieved by the use of the pareira brava, will be found in this journal for October 1832, and several

similar cases have since that time come under my care.

Acute Inflammation of the Muscular Structure of the Bladder.

The symptoms of this complaint are acute pain and sense of tightness in the region of the bladder; and at first a difficulty in passing the urine, each effort being attended with straining and shiverings. The water is voided, soon after the commencement of the attack, drop by drop, and then complete retention takes place. The abdomen becomes distended, the patient complains of darting shooting pains all over this region, and particularly in the rectum. The pulse is hard and quick; there is great heat, thirst, restlessness, anxiety, and nausea. The urine is very red, sometimes bloody, and of a high specific gravity. The severity of the symptoms will, in a great degree, depend on the extent of the inflammation and the causes which have produced it. In the early stage, the disease usually affects the neck of the bladder, in which case there is commonly retention of urine. Sometimes the inflammation occupies that part of the bladder in which the mouth of the ureters are situated: these then become involved in the affection, and a suppression of urine more or less complete, and its consequences, ensue. In this case there is commonly pain and tenderness on pressure in the hypogastrium. When the posterior portion of the bladder is affected, the rectum suffers more particularly, and the patient is harassed by a most distressing tenesmus.

Idiopathic inflammation of the bladder is not a common disease, and is usually caused by exposure to cold and indulgence in spirituous liquors. Sometimes it is connected with gonorrhœa, either occurring from the extension of the inflammation in the urethra, or produced by the action of the remedies which are given in the treatment of the complaint. The retention of urine in the bladder, after the desire to void it has been felt, is a very frequent source of mischief, and frequently brings on an incurable disease of the bladder. The chronic form I believe to originate most commonly from this cause. Stone, the incautious or violent use of sounds or catheters, will cause the complaint. The symptoms of this disease are so severe,

* “La racine de parera-brava est un spécifique contre toutes les maladies des reins et de la vessie qui sont curables. Il agit avec tant de douceur qu’il n’y a point d’occasion où l’on ne puisse l’employer sans en craindre de mauvaises suites, et on peut comparer ses effets aux effets spécifiques du quinquina, de l’hypecacanba, et de l’alum.”—*Traité des Maladies les plus fréquentes, &c. par M. Helvetius. Liège, 1711.*

† Dr. Prout recommends an acetous extract of colchicum, in doses of one or two grains at bed-time, prepared by Garden, of Oxford-street. I have given this preparation an extensive trial, and can bear testimony to its excellence.

and its progress so rapid, that the surgeon must lose no time in adopting prompt and decisive measures for the relief of the patient. General bloodletting, the application of leeches to the pubes, the drawing off the water by the catheter, if the bladder be distended, is the treatment which must be instantly resorted to: opium, in full doses, or if there be no tenesmus, opium in combination with calomel, should be given, and repeated every four hours. If these measures be employed early, the patient soon experiences a diminution of his pain, the water is passed in greater quantities and with less suffering, his constitutional symptoms improve, and he then falls into a sound and refreshing sleep. If, on the other hand, these measures be delayed, the symptoms which have been before described become aggravated, and delirium and death ensue. On examination after death, the muscular parietes of the bladder will be found to be gangrenous; and if there has been retention for a long time, it will be found to have given way, and the urine to have escaped into the pelvis. The mucous membrane will be found of a dark, livid colour. The following case was a well-marked one of this form of the disease:—

Inflammation of the Bladder.

Benjamin Spicer, night watchman, aged 69, was admitted at the General Dispensary, October 22, 1832, for an affection of the bladder. There was considerable pain in the region of the bladder, increased by pressure, an inability to pass his urine, darting, shooting pains in the rectum, dull pains in the loins, and sickness. His pulse was full and quick, countenance anxious, tongue dry, great thirst, bowels open. The urine was immediately drawn off by the catheter: it was acid, and very high coloured. Twenty leeches were applied to the pubic region, and a dose of opium was administered. Hot fomentations to the part, and an injection at night. This plan of treatment was continued for a week, under which he recovered from all the urgent symptoms of the attack. For the last three years, he had been occasionally subject to slighter attacks of this kind, and I therefore thought that the decoction of the *pareira brava* might now be administered with advantage. He continued taking this medi-

cine for three months, under the use of which he perfectly recovered.

But it not unfrequently happens that after an acute attack of this disease, the bladder never recovers its usual tone, and the chronic form of the complaint supervenes, which is extremely distressing, and, I regret to say, seldom cured. There is uneasiness about the region of the bladder; frequent desire to make water, both by night and day; sometimes it passes off involuntarily; uneasiness about the rectum, and occasionally prolapsus of the gut; sallowness of the countenance, mouth dry, and appetite bad. The urine is generally acid, and often contains no more mucus than natural; at other times some may be seen floating in the urine. Impotence is generally the effect of long continuance of this disease.

When this disease, as frequently happens, is caused by long standing strictures in the urethra, and enlargement of the prostate or prostatic calculi, it is clear that the primary affection should especially engage our attention. But even when the primary disease has been subdued, the inflammatory complaint of the bladder often remains. There are few, if any remedies, that have any decided effect on this disease: those which I believe to be the most efficacious, are the *pareira brava* and the *buchu* (*diosma crenata*). In some of these cases, where the bladder is known to be very much thickened, mercurial friction has been strongly recommended, and instances related of its success.

On dissection, the bladder will be found more or less thickened, and its inner surface presents a considerable number of rugæ, caused by the projection of the enlarged fasciculi beneath. The thickness of the bladder is sometimes very considerable. Dr. Baillie has given the representation of a bladder nearly an inch in thickness. The prostate gland is enlarged.

The peritoneal covering of the bladder is also sometimes inflamed, and adhesions form between it and the rectum or uterus in females, and sometimes even adhesions form between the bladder and omentum. When this affection exists, the disease usually spreads to the peritoneal covering of the adjacent parts, and symptoms of general peritonitis supervene.

Persons of a gouty and rheumatic

diathesis are frequently subject to diseases of the urinary organs. In fact, some writers, among whom Soemmering deserves to be particularly mentioned, assign suppressed gout as a frequent cause of the inflammatory diseases of the bladder, particularly in old persons; and Dr. Prout, in his valuable work on Calculous Diseases, describes a particular kind of inflammation of the urinary organs, to which gouty individuals are subject.

"In gouty individuals," says Dr. P., "who have likewise suffered from urinary derangements, a severe affection, ultimately involving the whole urinary system, and which, for want of a better name, must be termed *inflammatory*, though the circumstances attending it differ altogether from those of common inflammation, sometimes occurs. Hitherto I have only seen this affection take place after an irregular attack of gout. It commences with slight rigors, followed by feverish exacerbations, and accompanied by unusual prostration of strength, and mental depression. These symptoms of constitutional derangement soon assume a more violent character; the pulse becomes excessively quick; the skin hot and dry; the stomach oppressed with nausea and vomiting; there is tendency to delirium, and, in short, to all the symptoms of irritative fever of the most formidable kind. At this time the secretion and excretion of the urine are not apparently affected; and the patient, though repeatedly urged on the subject, declares he has no pain, either in the urinary system or elsewhere, nor does he complain when examination or pressure is made. These symptoms go on increasing in spite of every remedy, when at length the external organs sometimes become tumid, and retention of urine, more or less complete, is perceived for the first time. The powers of the patient now sink rapidly, the whole tumid urinary organs acquire a dull livid hue, and death speedily closes the melancholy scene."

I have only seen one case of this kind, in which the symptoms resembled those described by Dr. P., except as regarded the excretion of urine; which was very frequent, and attended with great pain.

CONTINUED REMARKS

ON

THE USE OF CALAMINE IN CONFLUENT SMALL-POX.

To the Editor of the Medical Gazette.

Sir,

THE following case is partly related from memory, but the general statement is correct. It paints a horrid scene, but no language could adequately describe the patient's sufferings and struggles. He had certainly more than twelve epileptic paroxysms in the progress of the disease.

I am, sir,

Yours most obediently,

HENRY GEORGE.

Phillimore-Place, Kensington,
August 10, 1833.

A gentleman, 21 years of age, on the 27th of June felt severely indisposed; suffering from rigors, intense pain in the head and back. Early in the evening of the 28th some spots were observed about the face and body. He retired to bed, passed a wretched night, and on the morning of the 29th I first saw him. His mind was wandering; his limbs and voice tremulous; his tongue dry, and covered with a brownish-red crust; his pulse 120; his face was swelled, and covered with small-pox pustules; his bowels had been relieved, and he had voided plenty of urine. The nourishment to consist of beef-tea, arrow-root, &c. and I directed the following medicines:—

R Liq. Amm. Acet. ʒiss.; Amm. Carb. gr. xij.; Sp. Ether Nit. ʒss.; Tinct. Hyos. ʒss.; Aq. Puræ, ʒj. M. f. haust. 6tis horis sumend.

June 30th.—Had passed a tolerable night, about four hours' sleep; takes his nourishment; the face is much more swelled, and is one mass of eruption. Bowels open.

Cont. omnia.

July 1st.—Yesterday was passed in great restlessness and agitation. His appearance is now frightful; the whole surface of the body, with the exception of the abdomen, one mass of eruption, and, excepting a small space on each temple, there is not the least portion of sound cuticle to be seen over the whole

face : the ears also are covered with the eruption, and the whole skin of a dark livid colour. Early this morning he had a violent epileptic paroxysm, which lasted some time, requiring five persons to restrain him. On the cessation of the fit, I endeavoured to administer an enema containing two drachms of laudanum, but owing to the violence of his struggles one-half of it was lost. I directed the following medicine to be given, and ordered wine, whey, beef-tea, &c. for his nourishment :—

R Amm. Carb. ʒss.; Acid. Cit. ʒss.;
P. Ipec. comp. gr. xij.; Sp. Ether Nit.
ʒij.; Aq. Puræ, ʒij. M. f. mist.
cap. dim. stat. et post. hor. 3 repet.

10 o'clock, P.M.—Has taken plenty of nourishment—taken it even with avidity. Has had another fit. Has slept a little. His appearance now is truly distressing : trembling every limb, conscious of your presence, recognizing every one, but rambling and talking in all the wildness of furious insanity. Has passed plenty of nervous urine; pulse very rapid; skin hot and moist. I succeeded in injecting an enema containing two drachms of laudanum, and directed the wine-whey, with beef-tea, to be given frequently during the night.

2d.—Had four hours' sleep in the night; is more tranquil, but still very much disturbed. Passed plenty of urine. Administered a soap injection, and continued his nourishment.

10 o'clock, P.M.—The bowels have been relieved twice. No alteration in symptoms. Repeated the injection, with two drachms of laudanum.

3d.—Has had some sleep in the course of the night. Retention of urine, the bladder reaching to the umbilicus; introduced the catheter. Continued his nourishment, covered the whole body with the calamine, and ordered the following medicine :—

R Ammon. Carb. Acid. Citric. aa.
gr. xv.; Sp. Ether. Nit. ʒss.; Tr.
Cinch. c. ʒj.; Tr. Opii, gtt. vj.; Aq.
Puræ, 5x. M. f. haust. 6tis horis.

10 o'clock, P.M.—Introduced the catheter. Another fit has occurred during the day.

I will pass over the six following days. The medicines were continued, and castor-oil or rhubarb occasionally given. I was compelled to use the catheter night and morning, until the morning of the 6th; and on the 7th an

attack of diarrhoea was restrained by the use of chalk and opium. In this interval it was necessary to watch him closely, as he shewed every disposition to destroy himself. On the 5th his abdomen had become tympanitic.

9th, 10 o'clock, A.M.—Had a violent epileptic paroxysm in the night; presents at this moment the most horrid spectacle that can be imagined; lies, and while lying trembles from head to foot; his countenance suspiciously wild, and expressive of the darkest intentions; recognizes every one, and answers collectedly to any question, but his mind immediately wanders. Has not closed his eyes for two nights and days; urine plentiful; bowels open; innumerable pustules have been opened by his parents and attendants, and are now healed. There is not the smallest portion of exposed cutis to be seen any where. There is no swelling of the extremities, and the face, which has been completely peeled of its cuticle, (this was accomplished without difficulty, and occasioned scarcely any suffering,) is not at all swelled. The eyes are now open, and the incrustations formed by the powder are now in places falling off, exposing a perfectly smooth skin. A considerable abscess under each great-toe and one heel has been opened, discharging thin putrid matter mixed with blood: the smell was dreadful. I directed ten grains of soap and opium pill to be given immediately, and four grains to be given every two hours until sleep was procured, continuing his nourishment, which, for the last two or three days, had consisted of strong beef-tea, egg and wine, ale, &c.

10th, 9 o'clock, A.M.—Has taken ten of the pills; has passed a more tranquil night; the *trembling* has ceased; gave a dessert-spoonful of castor-oil; continued his nourishment, and the draughts with ammonia, &c. nearly as before.

I will now pass on to the 24th. During this interval, many of the usual difficulties were encountered. At his earnest request, animal food has been allowed him daily. The following circumstances I relate entirely from memory; any inaccuracy can only relate to time (a day or so). On the 14th, the incrustations formed by the powder on the face had been totally removed, leaving the skin perfectly smooth, having a florid appearance, and, but for the expression of the eye, his countenance was

healthful. From this time to the present, incrustations have been forming on the site of each pustule, and on removing them slight depressions are to be observed: these, I have no doubt, will gradually disappear. The error, I believe, was in removing the incrustations, as they loosened, instead of applying more calamine and still longer excluding the atmosphere. I had forgotten his face, from my anxiety for his life: all this was done by his attendants, and the face rubbed over with oil without my observing it. Yesterday circumstances induced me to administer some purgative medicine: it operated twice. Immediately after the second operation, which was liquid, he had a most violent fit; a consultation with an eminent physician followed, and the following medicines were ordered:—

R Muriat. Morphicæ, gr. j.; Acid. Muriat. m.j.; Aqua Distill. ʒj. M. f. solut.

R Solut. Morph. m.x.; Decoct. Cinch. ʒx.; Tr. ejusd. ʒj. M. f. haust. 6tis horis.

26th.—We again met in consultation. There had been no return of the fits, but he was restless; little or no sleep; the urine, which hitherto has been so copious, is now very scanty, and depositing largely.

R Ferri Carbon. ʒss.; Aq. Puræ, ʒx. M. f. haust. 4tis horis.

27th.—Appears going on well; has passed plenty of urine.

August 5th.—He has gone on with the carbonate of iron, the dose of which has been increased to two scruples. Has had no fit; has been gaining strength, and even flesh; his bowels have acted daily without medicine, and the urine has been plentiful. His appetite very keen, which has been indulged; his mind much stronger, but he is still occasionally rambling and very irritable.

CASE OF THORACIC HERNIA.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case sufficiently interesting for publication, you

298.—XII.

will oblige me by inserting it in an early number of your valuable journal.

I am, sir,

Your obedient servant,

W. F. MORGAN,

Late House-Surgeon to the Bristol Infirmary.

22, College Green, Bristol,
August 5, 1833.

James Tarr, ætat. 54, a mason by trade, was admitted at the Bristol Infirmary, under the care of Mr. Richard Smith, July 20th, with a fractured leg, occasioned by a heavy stone falling on the limb; the bones being comminuted and the soft parts severely bruised. Considerable swelling, with vesication, followed; unattended, however, by much constitutional disturbance. This had in a great measure subsided, and the patient appeared to be doing very well until the seventh day after the accident, when delirium came on, succeeded by great prostration of the vital powers, and he died on the following day. The symptoms, during the last few hours of life, bore a striking resemblance to those of the concluding stage of enteritis; the abdomen being tympanitic and tense; the general surface of the body bedewed with a copious cold perspiration; the extremities cold and livid; the pulse very frequent, small, and feeble; and the respiration frequent and laborious. The delirium which ushered in this change was unattended by any sign of arterial excitement about the head, and was not of a violent character: it continued in a less degree nearly to the last. There was no evidence of any inflammatory affection either in the chest or abdomen, except the resemblance of the latter symptoms to those of a person dying from enteritis, as before-mentioned; and the state of the pulse, skin, tongue, &c. with the aspect and manner of the patient, all indicated from the first great prostration. The case, therefore, had much the character of that derangement of the nervous system, with the giving way of the powers of life, which is sometimes observed after serious injuries; but here the shock of the accident had previously scarcely been felt, and the patient appeared to be doing as well as any other with an ordinary fracture. A soothing and moderately antiphlogistic treatment was employed for the injury in the first instance; and when this unfortunate change took place, stimu-

lants were obviously called for, and freely administered. On examination after death, a thoracic hernia of remarkable extent was discovered, comprising the whole of the stomach, nine feet of the small intestines, and four feet of the colon, with the omentum, which had passed into the left side of the chest through an aperture in the diaphragm. The left lung was lying close to the spine, compressed into a bulk not larger than the spleen, and the heart was pushed over to the right of the mediastinum. The right lung also was unusually small and dense. The perforation in the diaphragm was of a circular form, measuring three inches and a half in diameter, and was situated in front and to the left of the œsophageal opening, but quite distinct from it: its edges were smooth and elevated, and covered by a serous membrane; evidently shewing that it was not of recent origin. The remainder of the muscle on this side was pale and attenuated, but not softened; and that at the base of the right side of the chest was perfectly healthy. The œsophagus entered the abdomen at the usual spot, and immediately turned back upon itself to terminate at the cardiac orifice of the stomach, which lay within the chest at the margin of the lesion in the diaphragm. The stomach was much distended by flatus, and lay behind the other viscera, with its greater arch uppermost towards the neck, and the pyloric extremity, like the cardiac, close to the opening in the diaphragm. The duodenum proceeded from this point towards Glisson's capsule, and took its usual course. The hernial portion of the small intestines was the lower part of the ileum, terminating six inches from the cæcum; and that of the large intestines was the arch of the colon, with the loose portion on either side of it. The bowels, like the stomach, were much inflated, and with it completely filled the left side of the chest, which was evidently enlarged by their pressure.

Not the slightest strangulation existed, and the hand could be passed with ease between the displaced viscera and the sides of the opening. Some old and firm adhesions connected the omentum to the pleura near the clavicle; on dividing which, the whole of the protruded parts were readily withdrawn from the chest. With the exception

of a little inflammatory blush on the colon, no other morbid appearances were discovered, and the rest of the thoracic and abdominal viscera were as usual in all respects. The corpse was muscular and robust.

The curious and interesting feature of this case is the length of time that the hernia had probably existed. The examination clearly proved that its date was long antecedent to the recent accident; besides which, the fracture of the leg was occasioned by a local cause which affected no other part. On inquiring into the man's former history, his friends stated, that thirty-eight years ago he had received a violent blow on the back by the fall of a tree, which, they say, pressed out the contents of his stomach through the mouth: since then he had never enjoyed good health, and often complained of asthmatic dyspnoea, and was subject to dyspepsia and constipated bowels. It did not appear, however, that he suffered much inconvenience, as he was always able to follow his employment.

CASE OF FRACTURE OF THE JAW.

To the Editor of the Medical Gazette.

SIR,

IN the number of your journal for the 27th of July last, there is a paper by Mr. Lonsdale on Fractures of the Jaw, with a drawing of an instrument invented by him to be used in such cases. This instrument is ingeniously contrived, and may answer the purpose in many cases; but as I suspect it will not answer in all cases, on account of the irritation attending such injuries, which are often effected with much violence, and complicated with other severe injuries, I beg the favour of you to insert in your valuable journal the following case of compound fracture at the symphysis of the lower jaw, which will furnish a hint for an additional means of cure in some of these cases:—

On the 18th of December, 1817, Robt. Entwistle, aged 20 years, a private in the 1st Dragoon Guards, a troop of which was stationed in this town, had his lower jaw fractured by a kick from his horse. He was cleaning the horse's

hind foot, when on a sudden something in the stable yard startling the animal, he gave a violent kick, which fell on the man's lower jaw with such force as to throw him backwards to the ground; by the fall he also received a wound in the occiput. When I saw him, which was very shortly after, he presented a horrible figure: blood and saliva were flowing copiously from his mouth; there was a wound at the apex of the chin, through which I passed my probe to a fracture in the bone; and he was in great pain. On looking into his mouth, there was a fissure which divided the bone and the gum of the lower jaw exactly in two, at the symphysis; the row of teeth on the left side was nearly half an inch raised above the teeth on the right side. I found I could move the sides of the jaw, so as nearly to restore them to their level; but on removing my hands, they instantly separated to their former distance. Two or three teeth were broken, but none pushed out.

I dressed the wound on the chin with a little simple ointment; the wound on the occiput, which was but a slight one in the scalp, I also dressed in the same manner, and applied a simple roller over the head and under the jaw. I saw him a few hours afterwards on the evening of the same day, and found him suffering excruciating pain in the head: his pulse was full and strong. I took about a pound of blood from his arm, and gave him a dose of calomel and jalap. On the following morning his head was much easier, his medicine had operated well, and his pulse was much reduced. He had still a good deal of pain about the fracture: I dressed his wounds, and bound up his head with the four-headed roller described in Benjamin Bell's System of Surgery. This answered very well, and kept the bones fixed properly; but finding in a day or two that the part of the roller which passed over the top of the head was apt to slip, instead of passing the ends over each other, and pinning them by the sides of the ears, I crossed them at the top of the head, and pinned them at the front and back of the head to the other slips that came from the chin. This kept all well together, and the patient said that no other bandage that was tried on his head answered so well as this. He was fed entirely on spoon meat.

In a few days after the accident he still complained of much pain in his mouth. On examining his teeth, one of them at the edge of the fracture was loose, and he had a good deal of pain at that part. I took this out, and there followed a quantity of coagulated blood, which appeared to have lodged there some days. After this he was much easier; the wound at the chin went on healing more rapidly, and was perfectly healed at the end of three weeks from the accident.

I applied some pasteboard splints under the roller at the chin, and kept them on for some days; but whether they were of any use I can hardly say. He seemed to derive the greatest advantage from the extraction of the tooth before mentioned; for, by the absorption of the alveolar process, union took place in such a manner that no vacancy was left between the teeth; and the rows of teeth on each side were reduced very nearly to the same level.

In six weeks from the accident, firm union had taken place; the man could masticate pretty well, and on looking into his mouth, it could not be perceived on first sight that any thing had been the matter. He was not at all disfigured externally: there was a very small scar left at the chin. He went at this time to his duty.

In December last (1832), exactly 15 years after the above case occurred, Entwistle called upon me, on his march through this town to Sheffield. On looking into his mouth, there was nothing to indicate that he had ever lost a tooth; and the line of teeth in the lower jaw was so little out of its proper level that I should not have noticed it, had I not looked particularly for it.

From the case above related, it appears, that if, in a similar accident, there should be any indications for taking out a tooth at the edge of the fracture, it may be performed without dread of that deformity, so unpleasant to young persons in particular, resulting from the loss of a front tooth. It is consoling to reflect, that after so great an injury, such a restoration may take place that the beauty and utility of the parts about the mouth and chin will be scarcely, if at all, impaired.—I remain, sir,

Your obedient servant,
BENJAMIN HUDSON, M. R. C. S.

Huddersfield, Aug. 12, 1833.

PRESENCE OF UREA IN THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

IN a contribution to one of your late numbers, some doubt seems to be cast on the existence of urea in the blood of patients labouring under anasarca with coagulable urine. Now as I have had opportunities of proving its presence in that fluid, it would be interesting to know the number of cases upon which this doubt has been founded; for since it has never been asserted that urea is present in every such case, it is by a number of experiments alone that a negative can be supported. I am not aware that the urinous odour (to which such importance has been attached as a source of fallacy) has ever been regarded as a satisfactory evidence of the presence of urea by any but your authors,—who expressly state, that until lately they considered it as determinate; notwithstanding that the crystallization on the addition of nitric acid has been used in these researches as the principal and most indispensable test. If urea were distinguishable by its odour alone, then the peculiar animal matter of the blood would be a serious obstacle to our inquiries; but since this latter principle differs most completely from urea in its re-actions, I cannot help thinking that it must require some ingenuity to confound one with the other. By the insertion of these brief remarks, you will much oblige

Your obedient servant,

G. O. REES.

Guy's Hospital, August 12, 1833.

ON MEDICAL NOMENCLATURE.

To the Editor of the Medical Gazette.

SIR,

IT has often been a matter of surprise to me, that the names which are intended to designate diseases do not explain the maladies themselves. We frequently observe that most important complaints are named after symptoms. Thus we have epilepsy, phthisis, &c. After all, epilepsy is merely a symptom of a dis-

ease, which may arise from various affections of the brain. The term phthisis is incomplete, for it does not immediately lead the student to the tubercular state of the lungs. Podagra is another of the inconsistent names with which our professional nomenclature abounds. In the first place, the foot is not the only part which is liable to the attack of gout; and in the next place, if it were, the name podagra does not explain any morbid condition of the synovial membranes or their surrounding structures. Again, rheumatism is employed to express a peculiar affection of the fibrous textures, and arthritis rheumatica one of the synovial tissues of the larger joints. Such terms as these are apt to mislead the student, or at least do not sufficiently impress the mind with the importance of considering and connecting the symptoms and pathology of disease together. We frequently hear persons explain their complaints much better than the best nosological systems. A painter, with palsied arms, has stated that "he has got the poison of lead in him:" this is the disease of which colica (pietorum) is merely a symptom. Hæmatemesis is another symptomatic name, which may enjoy a very extensive application. It occurs in several different affections. Hæmoptysis also may exist during pneumonia, aneurism, dilated heart, &c. Asthma may be symptomatic of pulmonic or cardiac derangement.

While some of our technicalities indicate too little, others appear to indicate too much: for instance, the termination *itis* is appended, it is said, to very active inflammatory diseases: thus we have pleuritis, pneumonitis, laryngitis, &c. Now we feel convinced that such terms are liable to be associated with active treatment, and it is proper that they should be so in some cases, but not in all. It is evident that they are not all equally relieved by active treatment, and we know that in certain stages of all these diseases it is inadmissible. We cannot expect that all diseases of the living body will admit of a pathological name, for the exact pathological condition of some obscure cases cannot be ascertained until after death, and even then the disease may be so complicated that it would be impossible to give it a particular name; but there are numerous diseases which would admit of a much more scientific and rational appellation than they at

present possess, and, as in other departments of medical science, a slow improvement has been effected, so in this a slow and certain improvement may be accomplished. We need only take pattern from the names which respectively belong to substances in a modern Pharmacopœia, in comparison with those of former Pharmacopœias: the modern names indicate the composition of the substances, while many of the former were vague and unscientific. If we employ terms more expressive of the disease itself, a more particular diagnosis will be instituted. Many uncertain names are applied to diseases, and the more we deviate from exact experience and observation, the more will blind empiricism and imaginary systems prevail.

It is full time that medicine be entirely constructed on the foundation of organism. The organic term, if we may so express ourselves, of gastro-enteritis, is much more satisfactory, and has led to more satisfactory results, than the vague one of fever; the former, according to many, constitutes the disease, of which the latter is a symptom. The difficulty of applying exact names in all cases, may appear by asking ourselves the following questions:—Who can tell the exact alterations which the fluids undergo? who can tell the material cause of hysteria? The field before us is immense. Of this we are certain, that organic medicine cannot be constructed on a ruinous foundation. A state of anæmia is distinguished by the name chlorosis. *Tic douloureux* may arise from a morbid condition of a nerve, which may be an idiopathic affection, or symptomatic of diseased bone, or an aching tooth. Anasarca designates an effusion of fluid into the cellular membrane. Typhus, chorea, and tetanus, are merely symptoms of diseases. Since the employment of percussion and the stethoscope, modern practitioners have been enabled to designate pulmonary affections much more readily and accurately. Surely some advancement in pathological knowledge has been made since the following sentence was written:—"Neither do our diagnostics serve to ascertain exactly the seat of the disease (pneumonia), nor does the difference of the seat exhibit any considerable variation in the state of the symptoms, nor lead to any difference in the method of cure*." It may be said

that percussion was resorted to long before the stethoscope was invented: this is true, but from what we can ascertain, it was not exercised in the same useful and practical manner as it is at present.

Your obedient servant,
C. J. B. ALDIS, M.B. Cantab.

Old Burlington Street,
Aug. 10th, 1833.

MEDICAL JURISPRUDENCE.

TIME OF BIRTH—TENANCY BY COURTESY,
ETC.

To the Editor of the Medical Gazette.

SIR,

IN your last number, Dr. Loeck has mentioned an instance in which, during parturition, the head and one arm of a child were born some time before the rest of the body, and the child cried and breathed freely while in this situation. No medical man, I suppose, would hesitate to give the same opinion that he did in this case; viz. that the independent existence of the child commenced at the time the respiration was so complete as to allow of crying and breathing *freely*. The English law would, no doubt, adopt the same view of the case, after the extensive latitude which was allowed in the case, *Fish v. Palmer*, in 1796, where the sounder opinion of Dr. Denman was rejected, in favour of that expressed by Drs. Babington and Haighton, who considered mere muscular contraction around the lips a proof of separate vitality. Even the Scotch law would probably allow the child in Dr. Loeck's case to have been born alive, since it not only *breathed*, but *cried*, which is the proof of vitality required in the Scotch courts. See the case of *Dobie v. Richardson*, in 1765.

Perhaps, however, some of your readers may not be aware that medical evidence upon this point will for the future be much less important than it has hitherto been, as the law with regard to tenancy by courtesy has been completely changed, in consequence of the first report of the Law Commissioners on real property, so that it will no longer be necessary to prove that a child has lived for a *second or two*, in order that the father should enjoy the tenancy by courtesy. The acts brought into parliament by the Solicitor-General contain clauses

* First Lines, 1802, p. 227.

by which the husband enjoys the advantages of tenancy by courtesy, although there has been *no issue* by the marriage, and also providing, where a landed heiress has married a second time, leaving issue by the first husband, that the second husband shall have a life interest in *half the property* only, the other half belonging to the issue of the first marriage during the life of the second husband, and the whole reverting to this issue at the death of the second husband.

I am not aware, however, that the ridiculous anomaly has been done away, by which the descent of landed property commences only at the time of birth, while a bequest is valid from the earliest period of conception. Dr. Loeck's case is therefore still interesting in some questions of real property, though not in the point of tenancy by courtesy, to which he has alluded. It adds another proof also of the correctness of Dr. Hunter's opinion, which has been called in question by some persons, that in a supposed case of infanticide, the child may have inflated its lungs, partially or completely, before it has been wholly brought into the world.

I am, sir,

Your obedient servant,

H.

August 10, 1833.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ATTACKS OF THE PRESS ON THE MEDICAL PROFESSION.

It almost excites our indignation to observe the manner in which some low-bred writers of the daily press vent their petty spleen against the members of our profession. "We do not wish to speak harshly of the present race of medical men," says a sagacious contemporary; and straightway follows a tirade in which the doctors are soundly rated for not putting a speedy stop to the ravages of the cholera. The *present*

race—"what a falling off is there!"—is specified, no doubt, as an antithesis to that which is gone by; while the inferiority of the advances made in physic is more than insinuated to be sadly contrasted with the progress of other sciences. Now all this is very pitiful; originating in pure ignorance, and in a vulgar desire on the part of the writer to address himself to the prejudices and the fears of the small tradesmen and apprentices, to whom his lucubration is addressed. He does not wish to speak "harshly" of the present race of medical men! Ill would it become any writer in whose bosom one generous feeling—one vestige of candour—one spark of gratitude, is to be found, to prostitute his pen in censuring the conduct of our profession on the subject of cholera. It would be difficult, we deliberately affirm, to adduce in the long records of our history a more striking instance of disinterested conduct than that which has been exhibited by the members of the medical profession, in reference to the visitation of this most formidable disease. Disregarding the danger of infection, an apprehension which, whether well-founded or not, very many unquestionably entertained—uninfluenced by the class of persons most frequently attacked (a class from whom generally no remuneration, and never any that was adequate, could be expected)—eager only to relieve, and to acquire the knowledge which might enable them to relieve still further—medical men were every where seen pressing to the squalid and miserable abodes in which the disease was chiefly to be found; and yet we are told, with all the gravity and confidence that belong to an undoubted truth, that the better-informed among us shun the haunts of cholera, either because it compromises our personal safety or renders us less welcome visitors among our wealthier patients. This is quite in

keeping with the conduct of the press towards us ever since the disease first appeared in England: it has been one continued system of misrepresentation and injustice, if not of cunning and falsehood, in which they have derived but too much assistance from the indiscretions of some blockheads among ourselves. But we do not purpose either to rail at such persons or to argue with them: the former would be but an unworthy occupation, while the latter would imply that they were capable of appreciating our reasoning. They who declared (as was done last year) that cholera did not exist in London at all, but was a thing “got up by the medical and surgical gentry;”—we say such writers will assert any thing, however monstrous; and they who have the faculty of stating as facts whatever suits them at the moment, have always a great advantage in discussion: they never lack a peg on which to hang an inference, however false.

But there is another and painful consideration forced upon our minds by those illiberal attacks; for though to lay it to our charge be, indeed, most illiberal, yet is the observation on which it is based but too true, namely, that cholera remains nearly as little amenable to treatment as when it first spread its alarm among us. All the various plans which human ingenuity could devise have been called into operation; every indication which rational medicine seemed to point out has been acted upon fully, boldly, and we might almost say extravagantly; every powerful agent (many of them without any thing but mere experiment to warrant them) has been tried;—yet who that views, with an impartial eye, the immense mass of contradictory statements which have been published, can venture to say that the result amounts to more than proving what will *not* cure cholera? That many have been killed by the remedies, none can doubt—that

as many would have recovered had they been left to the unassisted efforts of the system, may reasonably be conjectured; still we may, without being over sanguine, expect that the mortality will gradually diminish in proportion as useless or injurious agents are disused, and the patient left to the influence of the *vis medicatrix nature*, aided by those remedies which experience proves to be adjuvants, in however limited a degree.

One of the great obstacles to the progress of medical science is quite unknown to, or at least is entirely overlooked by, those who indict their malapert philippics against it; and that is, its ever-varying nature. It is absurd to compare it disparagingly with the exact sciences: in them, every step gained becomes a resting-place—a strong hold whence fresh advances may be made; the field to be conquered, the subjects to be mastered, the data to be worked upon, being ever the same. The mutual attraction of the heavenly bodies—the relative affinities between the minute particles of matter—the theory of numbers—the powers of physical agents—all these were the same when the human intellect first began to grapple with them as they are now. But it is not so with the phenomena of organization; for not only does disease vary in different races of men and in different climates, but changes are constantly supervening in the same individuals and in the same localities. The very improvements in the other arts and sciences which change the physical condition of man, also modify his diseases. Hence medicine is, and ever will be, a conjectural art; changing from year to year and day to day—requiring all the application and all the ingenuity of its cultivators to keep pace with the alterations in the world around them. When, therefore, we meet in society with wittlings who come over us with “wise saws and modern

instances," illustrating the imperfection of our art, the above, as it appears to us, is the kind of argument we should employ; not denying the fact, but explaining the cause, and shewing this to lie in circumstances above the reach of humanity—namely, in the ever-varying conditions under which the object of our study is placed—the modifications of the human constitution induced by the changes in society—epidemic states of atmosphere—the springing up of fresh diseases—and probably other still less appreciable circumstances; such, for instance, as the new but hitherto unscrutinized principle lately discovered in the air by Dr. Prout.

But still the cry of the ignorant is for "specifics." Where (we are asked, in the paper alluded to) — where would be the harm in the Government giving "a few thousands" for the discovery of a remedy for cholera? This assumes what we most peremptorily deny—that medical men have evinced a backwardness, or require any such stimulus to exertion: and again, it supposes that the disease is to be cured by a *coup de main*—some elixir—a dose or two of which is to set all to rights. The only effect of such an offer would be to bring forward a shoal of impudent quacks; for no really intelligent and respectable person would join in the competition. Then, again, who should be the judges? A parliamentary committee, we presume; by whom the reward would be given to some of the tribe of St. John Long, or Morrison, or Eady—probably with as much discretion as in the case of Mrs. Steevens, who obtained a recompense for dissolving stones in the bladders of certain individuals; the said stones being found in the said bladders after the decease of the parties. No; whatever be the course of cholera, let us not have a premium for knavery, in the shape of a reward to the discoverer of a specific for that disease, but let medical men be fairly

paid by the public for public services; and such we hold attendance on the indigent to be, during the prevalence of a pestilence. The rich fear; even the poor devils who throw mud at us in the newspapers, they too have their fears. The public, it is true, are unwilling to pay when they can avoid it; but they will much rather do so than be in bodily fear, and are naturally extremely anxious to keep the malady from their doors. Now, although we would have our brethren exhibit all the zeal, the benevolence, and the devotedness to their profession, which they did last year, yet would we have them stipulate for adequate remuneration; and if they are true to themselves they will obtain it—the gibes of the *Morning Herald* notwithstanding.

PROGRESS OF CHOLERA.

SPORADIC cases of cholera began to make their appearance about the beginning of July, but it was not till the 15th that the disease assumed an epidemic character. From this time, however, it became evident that the metropolis was destined to undergo another visitation of this formidable malady; and accordingly Bermondsey, the Borough, Westminster, Whitechapel, Bethnal-Green, and Marylebone, have all suffered more or less, and some of them rather severely, from it. The cases have not been so numerous as last year; and we are happy say to that indications are already perceptible of a diminution in the extent of the epidemic. In some districts of the metropolis, fever is beginning to shew itself, the appearance of which has repeatedly been observed to precede or accompany the cessation of cholera. With respect to the type of the disease, however, it has been generally observed that it is quite as intense as on its first irruption. Probably last season, before the characteristic symptoms and physiognomy of the disease

were sufficiently well known, many cases were called cholera to which that name would not now be applied, and consequently the rate of mortality is rendered apparently greater by the limitation of the term to the severe cases.

We stated last week that it was the intention of Government to appoint inspectors in the different districts of the metropolis, to report upon the subject. This proposal has since been carried into effect; and the result of their investigations, on which we found the information above given, may be regarded as, upon the whole, of a consolatory nature.

—

DEATH OF DR. DARWALL.

WE regret exceedingly to have to announce the melancholy death of Dr. Darwall, of Birmingham, which took place on Saturday last, in consequence of his having wounded his hand in making a post-mortem examination.

—

THE LATE M. PALETTA.

AMONG the many eminent persons who have been lost to science in the year 1832, we have to reckon Professor Paletta, of Milan. The following is a brief notice of some of the leading particulars of his life.

GIOVANNI BATTISTA PALETTA was born at Montecresati, on the banks of the Lago Maggiore, in the year 1747. He was educated by the Jesuits of Brieg, in the Valais, and in due time left the establishment of those reverend fathers with a large amount of general information: among other accomplishments, which proved subsequently to be of the greatest advantage to him, he was master of several living languages. At Milan he commenced his medical studies, and at that period there was perhaps no other school in Italy to compare with that of Milan: in addition to its vast hospital, it had then to boast of the names of Galiardi, Patrini, and Moscati, in the list of its professors. After availing himself of the instruction of these eminent men, with the highest promise, for a few years, he removed to Padua, where the illustrious Morgagni was followed by distinguished pupils sent from all parts of Italy and Germany. To

the influence of Morgagni and Scarpa may we most probably trace the decided preference which Paletta always displayed for anatomy—a study to which he consecrated a great part of his long life, and in the illustration and advancement of which he was so eminently instrumental. He had scarcely received his doctoral degree at this place, when the Empress Maria Theresa offered him a chair of anatomy in the intended university of Mantua. The project of founding an university at Mantua, though never put in execution, is one of those many good designs for which Italy stands indebted to the house of Austria: to do the latter no more than justice, however it may have treated, in other respects, its Italian possessions as the mere acquirement of conquest, it has been eclipsed by no government in the world in the encouragement which it has constantly held out to the cultivation of the natural sciences, and in particular that of medicine.

Paletta returned to Milan, with a high reputation for his professional attainments: he was now twenty-seven years of age, yet such was his ardour in the pursuit of knowledge, that he laboured still four years more in the schools, and it was not till 1778 that at Pavia he assumed the degree of doctor in surgery. The attractions of Pavia were at this time great: Scarpa was professor of anatomy; Malacarne, from Piedmont, filled the chair of physiology; Spallanzani was splendid in his lectures on natural history; Tissot, of Lausanne, and Joseph P. Franck, conducted that famous clinical institute which sent forth so many able practitioners; Tamburini, by his controversial powers, shook the Vatican, and earned for his writings the honour of an *auto da fé*; and the illustrious Volta was even then contributing to physical science the richest of discoveries. To all these illustrious men Paletta endeared himself by his brilliant qualities.

Upon graduating in surgery he removed to Milan, and was presently appointed second surgeon to the great hospital: he was also engaged in teaching anatomy and clinical surgery until the period of his appointment to the important office of surgeon in chief, in the year 1787. About this time he paid a visit to Paris on the invitation of an illustrious personage, and was introduced there to all the eminent practitioners of the day. His modesty and great ac-

quirements made him the admiration of all. He now returned to his important charge, and devoted most of his leisure to anatomical pursuits. His researches were published, for the most part in the form of contributions to various learned societies, of which he was a member: some of them are in Latin, distinguished by a pure and elegant idiom: his Italian productions are written in a concise and energetic style, which strongly resembles that of Allieri.

From his thorough knowledge of the German, he was enabled not only to announce to his countrymen the opinions of the surgeons of the north, but to contribute to his native literature translations of several German works: among those may be mentioned Rosenstein on the *Diseases of Children*, and Brüninghausen on the *Treatment of Fractures of the neck of the Thigh-bone*.

His treatise *de Nervis Crotaphitico et Buccinatorio*, 4to. 1794, is well-known for its exactitude and finish; nor are the papers on the *Tunica Vaginalis*, and the *Gubernaculum Testis*, inferior in any respect. In 1785 he published his work *de Structura Uteri*, with his *Researches on the Umbilical Vesicle and its Functions*. In his *Adversaria Chirurgica* are contained his interesting observations on, 1. The Causes of Lameness; 2. Experiments on Warm Human Blood; and 3. His Anatomico-pathological Remarks on Paralytic Syphilis. Among his memoirs on practical surgery we find his Researches on Lithotomy—On Vaginal Hernia—On Hydrocele in Women—On the Treatment of Uterine Polypi—and some remarkable Cases of Fractures. His *Exercitationes Pathologicae* are so well known that their contents need not any particular enumeration.

In the Annals of the Italian Institute are inserted three of his papers: 1. On Arm-presentations; 2. On Phlegmonous Inflammation of the Spleen; and 3. Considerations on Mercurial Trismus. With a view to encourage Omodei's periodical, the *Annali*, he contributed various papers to that work, among which we may notice his remarks on Facial Spasm—On Viper-bite—On Glossocoele, with Prolapsus of the Tongue—On Symphysiotomy—On Varices, &c.

All the works of Paletta evince him to be a judicious and conscientious observer, a clever surgeon, and a consum-

mate practitioner. Charged as he was for many years with the clinique of one of the largest hospitals in Europe, how vast was the field which was opened to his meditations! And splendidly did he avail himself of his position. What with his extensive and exact acquaintance with anatomy, his genius, and the situation which he enjoyed, Paletta was one of the ablest of operators. He was a member of most of the learned societies of Europe, and decorated with the orders of the Legion of Honour and the Iron Crown.

But proud as were his titles, those were the most dear to him which he possessed in the love of his fellow-citizens, the esteem of his professional brethren, and above all in the gratitude of the poor, who were ever an object of his care. Thus the news of his death, though long expected, was felt as a public calamity at Milan.

In his disposition he was kind and generous; not ardent, yet sensitive; laconic in his conversation, but clear and expressive; to strangers he was courteous and benevolently attentive.

He died of a severe dysentery on the 27th of August, 1832, in the 85th year of his age. All Milan assisted at his obsequies: the pupils of the great hospital carried his remains to the grave; and a public monument is to be erected to his memory. The monument, however, which he has left behind him, in the fame of his talents, his virtues, and his charities to the poor, is one that will long withstand the wreck of time*.

CLINICAL OBSERVATIONS

ON

HYDROCELE AND ITS PRINCIPAL VARIETIES.

BY BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

NOTHING is more easy than the diagnosis of simple hydrocele, nor is there any thing more certain than its treatment; so that were it not for the varieties and complications which are often to be met with, I should not take up your time with any general remarks on this malady. You all know that the name of hydrocele is applied to watery tumors of the scrotum, and that

* Abridged from the *Gazette Médicale*.

they are of two kinds: in one, the water is diffused in the cells of the cellular tissue—this is hydrocele by infiltration; in the other, it is gathered in a pouch—this is hydrocele by effusion. A third kind, moreover, is met with in practice, which is distinguished from the others by the accumulation of serosity in accidental serous cavities, formed either in the substance of the spermatic cord, or in the testicle itself, or in the epididymis. In offering you this classification, I should add that each kind may present a great number of varieties, the characters of some of which it shall be my present business to point out.

In the first place, let us describe the principal varieties which belong to the cellular tissue. In this tissue I have recognized four varieties:—1. The fatty cellular tissue, to be found in certain animals only, as the sheep, developed in the epiploon, and strongly marked in some cases. When an inflammation occurs in this tissue, it almost always terminates in a sort of shrinking, and a gathering of matter in the parts. It may be observed in strangulated hernia, where the epiploon is protruded, and in sheep which have been inoculated with variola, in order to save them from certain disorders. 2. The fibrous cellular tissue, which contains neither fat nor serosity. This tissue, in man, is mostly found about the articulations. The inflammation which occurs in it is almost always complicated with strangulation. In the dog and carnivorous animals, the cellular tissue is almost wholly fibrous. 3. The elastic cellular tissue, which contains none of the elements already mentioned. It is observed about those tendons which have no synovial bursæ. The inflammation which usually affects this kind, has a great tendency to spread, as in the palm of the hand, where the tendinous phlegmasiæ easily communicate with the fore-arm, &c. 4. The serous cellular tissue, which never contains any fat, is not elastic, but always bathed in a certain quantity of serosity. This is especially observed in the eyelids, in the genitals, the scrotum, &c. The inflammation formed in it often terminates in suppuration; and this is the tissue which becomes the seat of hydrocele by infiltration, idiopathic, or symptomatic.

Considered with reference to its situation, this hydrocele occupies the spermatic cord, or the middle portion of the cellular tissue, or in fine the serous, subcutaneous areolæ. In the first locality, the tumor is circumscribed, floating, and confined to one of the cords; in the second, it is more extended, reaching from the ring to the bottom of the scrotum, preserving the impression of the finger, and occupying only one of the bursæ; in the third, the tumor is voluminous, thickened, and readily

spreading over the whole of the scrotum, unimpeded by the median line. An acquaintance with these several cases is important as the treatment is concerned; for, supposing we were to let out the infiltrated fluid, in the first two kinds, we must make incisions more or less extensive; whilst in the third, a simple puncture of the skin would often be sufficient to discharge the whole of the fluid contained in the areolæ of the subcutaneous tissue, by reason of the extensive communications which exist throughout it. Idiopathic hydrocele by infiltration only occurs in new-born children and in old men: it may be limited to one side, or extend to the whole of the scrotum.

Hydrocele by effusion, of which I mean principally to treat, is fluctuating: it rises from the bottom of the scrotum towards the inguinal canal, is almost always developed in front of the testicle, and offers no very particular resistance, except when the serous pouch and the other tunics, distended and thinned, react on the distending fluid. These depositions, however, are susceptible of variety, as the following case will serve to shew:—

CASE I.—*Hydrocele by Effusion, complicated with Injury of the Cord.*

A man came to the Hôtel Dieu, after having been treated in another hospital for hydrocele, by the method of puncture. The operation, he said, had been very painful, and nothing came off by the canula except blood—no serosity. The scrotum, instead of diminishing, had immediately increased in volume. It became hot, painful, and tense; and it was only by a strict antiphlogistic regimen that it was brought back to the state in which it was previous to the operation. M. Dupuytren having examined the tumor by the light through a bougie, discovered it to be transparent in all its posterior portion, while in front, and about the place where it had been tapped, it was opaque, apparently with the substance of the testicle. Holding the part by its opaque portion, he emptied the tunica vaginalis by a puncture made behind.

It is thus that hydrocele by effusion may become complicated with encysted hydrocele of the cord. This variety has been the cause of frequent error in diagnosis: having its seat very often in front of the inguinal ring, and extending even sometimes into the interior of the canal, it presents a great resemblance to inguinal hernia, for which it has often been mistaken. While these two maladies are apart they are easily distinguished: the tumor of the cord is above—that of the serous tunic of the testicle is lower down. When they exist together and contiguously, the

hydrocele of the tunica vaginalis goes in front of the other. It sometimes requires great attention to acquire a clear understanding of the state of the parts. The patient must be made to lie on his back, when the tumor is commonly perceived to be rounded, circumscribed, isolated, and distinct from the intestine or the epiploon: then there is transparency, with fluctuation, to aid us further in our diagnosis. The following case, however, will shew that there may be great difficulty after all in coming to a decision, and that M. Dupuytren was right in reserving his opinion in this instance as to the real nature of the disease.

CASE II.—*Encysted Hydrocele of the Sper-matic Cord—Treatment by Incision.*

A boy of twelve was operated on, in 1828, for a hydrocele of the tunica vaginalis of the left side. He was treated with injection, and went out perfectly cured. Some months after there appeared in the groin, in front of the inguinal ring, a tumor of soft consistence, indolent, and fluctuating, without any change of colour in the skin. It was taken for a hernia, it would seem, for a bandage had been ordered; but in spite of the application of the latter the tumor enlarged, and the patient once more came into the Hôtel Dieu for the benefit of M. Dupuytren's assistance. A rounded and rather an oblong tumor, of about the bulk of a pigeon's egg, was found in front of the ring: it began at about half an inch from that spot, and terminated near the epididymis. Notwithstanding its tension, it was fluctuating, and there was no discoloration of the skin. When the patient coughed, the hand applied to the tumor did not feel any peculiar movement. It could be pushed into the ring, but it was evidently an isolated swelling: it was moreover very evidently transparent. These several characters leaving no doubt on M. Dupuytren's mind of the presence of an encysted hydrocele, he resolved to treat it by the method of incision.

The operation was performed in October, 1829. The patient having been laid on his back, an incision was made through the skin covering the tumor, with as much care as if a hernia were present. Two difficulties, in fact, were to be avoided—an error in diagnosis, and lesion of any of the parts forming the cord, the connexion of which with the sac it was not easy to determine. The subjacent layers were now successively opened, until at last a cyst was reached. A jet of serosity shewed that its interior was arrived at. The opening was enlarged with bistoury and scissors; the finger introduced into the cyst could not detect any communication.

Having removed all the fluid, the cavity was filled with charpie, in order to provoke inflammation and the adhesion of the parietes. No accident occurred: the charpie was removed. In the course of some days a moderate inflammation set in, attended by an abundant suppuration. In twelve days the wound was cicatrized.

I have seen, said M. Dupuytren, hundreds of cases of encysted hydroceles of the cord taken for hernia, and treated with the application of bandages. In one individual thus treated, the tumor, continually pushed back, had ascended into the inguinal canal, but it acquired a very great bulk. The uncertainty which exists in such cases as to the nature of the tumor, whatever signs we may have to guide us, ought in some sort to model the treatment which we should employ.

Relative merits of Incision and Injection.

The method of injection is one of the best, the most prompt and simple, that can be adopted for encysted hydrocele. But if an error of diagnosis be committed, and an irritating liquid be thrown into a hernial sac, the consequences must be alarming. Nor is such an accident supposititious: an injection of an irritating liquid into the belly has been practised in the operation for vaginal hydrocele, which preserved its connexion with the peritoneum. In one case, the injection did not prove fatal; but in another, it brought on a peritonitis, which soon ended in death. There is need, therefore, of an extreme caution lest the life of the patient be put in jeopardy; and if an injection be required, it should be done with at least the precaution of applying the fingers to the abdominal ring, in order to interrupt any dangerous communication.

Whenever the least doubt—the least uncertainty—exists as to the nature of the case, some other method than that of injection ought to be adopted. Incision of the cyst removes all apprehension in this respect, and appears worthy of a preference in all cases of the kind. It is further important to observe the difficulty—not to say the impossibility, of determining precisely the relations of the spermatic cord with encysted hydrocele of the part. For which reason, in the practice of incision, the several tissues should be divided with slowness and caution.

With respect to its form, hydrocele presents several important varieties. Thus the tumor, which is usually unique and regular, is occasionally strangulated towards its centre: this is the *hernia en bissac*, the two parts of which still preserve a communication.

CASE III.—*Hour-glass variety.*

In the year 1824 a patient came to the Hotel Dieu having a remarkable example of this variety: one part of the tumor occupied the scrotum, whilst the other was situated in the abdomen, and puffed out above the ring. This last was the place of the middle contraction. When the patient was in an erect position, the fulness of the tumor was more perceptible: when he coughed, it became tense; when he lay down, on the contrary, it collapsed. The abdominal part of the tumor and the right iliac region which it occupied, were increasing in elevation and volume. The transparency of the external tumor, and the manner of its growth, sufficiently characterized a hydrocele in which the tunica vaginalis was engaged, and in which this latter part, after undergoing a contraction about the ring, was again dilated internally in the abdomen.

In the interior of simple hydroceles there are sometimes found cells more or less numerous, containing the fluid, in such a manner, that when puncture is practised, only a small part of the fluid runs out, and one would be obliged to repeat the process on all the cells if it were wished to discharge it all. In cases of this kind, which we may recognise as resembling what I have described in regard to hernia, the parts being multilocular, incision ought clearly to have the preference rather than puncture or any other method. Yet there are exceptions, as the following case will testify:—

CASE IV.—*Bilocular variety, treated with puncture.*

A man came to the Hotel Dieu about the beginning of May this year (1833), complaining of a tumor which he had in the left side of his scrotum. Eighteen months previously he had received a blow on the testicle: from that time the part became swollen unequally. When M. Dupuytren examined it, he found it to consist of an irregular, fluid, fluctuating, and transparent mass. Attributing the irregularity of its shape to the resistance of the tunica vaginalis, he plunged a trocar into the most voluminous part of the tumor, when a quantity of a yellowish serosity was discharged; but scarcely was it reduced one half. In the most prominent part of the remainder, M. Dupuytren still found a marked fluctuation. He made a second puncture. An abundance of a muddy liquid now made its appearance, and the bursa of the left side was brought to its natural size. The first liquid coagulated by heat; the second underwent no change; though the examination made at the Pharmacie Centrale shewed that this

second liquid was nothing else than albumen. The cord was in the same state as that of the opposite side, and presented no symptom of effusion.

This case appears to me of importance; for it sometimes happens that hydroceles regarded as multilocular, are in reality nothing more than hydroceles of the tunica vaginalis complicated with an encysted condition of the cord. Dr. Loir presented the clinique not long ago with a preparation which leaves no doubt of the fact. The spermatic cord distended by a liquid, in other words a hydrocele of the cord, was floating in the serosity which filled the vaginal cavity, and formed the base of the tumor: thus composed of two distinct hydroceles, it was extremely difficult to distinguish one from the other. But if observation proves that the complication of these two hydroceles may sometimes deceive, as if it were a multilocular one, observation has also convinced me that there exist hydroceles the pouch of which cannot be emptied by a simple puncture, and that this condition is owing to a multiplicity of cells retaining the liquid.

Congenital Hydrocele.

Hydrocele of the tunica vaginalis presents remarkable varieties also, according as it occurs in adults, or as it is congenital. It is well known that in the fœtus, before the period of birth, the testicle is up in the abdomen, and that it often does not come down till after birth. The prolongation of the peritoneum by which it is accompanied, and which at a later period forms the tunica vaginalis, becomes closed in general some time after the descent. It may happen, however, that before this takes place some water may escape into it from the cavity of the belly. Hydrocele is the consequence; and this kind is called the congenital variety. It may be removed by mere pressure, restoring the fluid to the belly again. I have proved, said M. Dupuytren, that this species of hydrocele may show itself while yet the testicle is shut up in the abdomen, and is found placed behind the superior orifice of the inguinal canal. The mechanism of its occurrence is easy enough to be understood. That part of the peritoneum which serves to envelop the testicle with a vagina, and which corresponds with the abdominal opening of the inguinal canal, being pressed either by the liquid contained in the belly, or by the intestines and omentum, yields insensibly to the pressure, extends, becomes engaged in the passage through which the testicle has to go, and is finally carried to the fundus of the scrotum. In this bursa, then, we find a fluctuating, translucent, soft, pyriform tumor, which disappears almost wholly under pressure exercised upon

it, or in the horizontal posture; but which, when left to itself, resumes, when the patient is erect, its ordinary shape and volume. I have also recognized a second variety of congenital hydrocele, which is distinguished by the same prolongation of the peritoneum, while the testicle is still engaged in the inguinal canal. The body of the tumor in both these varieties is only clothed by the teguments of the scrotum, by the subjacent cellular tissue, and by the cellulo-fibrous surface of the *fascia superficialis*. The upper portion is engaged in the ring of the great oblique muscle, and the testicle is adherent to the posterior wall of the passage, as it would be to the bottom of the tunica vaginalis. In fine, the abdominal orifice of the hydrocele communicates with the cavity of the peritoneum by a small opening. Both these varieties ought to be examined with much care, as they are liable to be confounded with hernias, which in the same way develop themselves from above downwards.

Hydrocele complicated with Hernia.

Among the accidents with which hydrocele often becomes complicated, we should not forget hernia; it is chiefly in old subjects that this complication occurs. In general the hydrocele passes in front of the hernia; sometimes, but very rarely, it glides behind. Some surgeons, in such a case, propose to leave the tunica vaginalis untouched, and to open only the hernial sac. I have however shown, that this is only sparing the hydrocele, when it might be remedied by a simple prolongation of the incision to the bottom of the sac, where the fluid still remains. Stubborn inflammations and various accidents ensue, which might be avoided by opening at the same time the serous tunic of the testicle. By complying with the latter indication, not only is the strangulation removed, but the hydrocele may be radically cured.

It sometimes happens that when the hydrocele is in front of a hernia, part of the omentum or intestine passes across the tissue which embraces the tunica vaginalis, and projects amid the fluid which constitutes the hydrocele. These secondary tumors are covered by the hernial sac, and by the serous tissue of the tunic of the testicle. In six cases of this kind which I have witnessed, twice have I seen symptoms of strangulation, resulting from constriction of the organs at the place where they are engaged in the serous pouch of the testicle. In those subjects who presented this condition, the soft and indolent hernia, at its upper part, acquired below, where it corresponded with the hydrocele, sensibility and resistance, and all the symptoms of strangulation. It then became necessary to divide the tunica va-

ginalis, filled with serosity. Presently the prominence of the secondary hernia was exposed; and having opened the sac, the aperture was relieved by which the viscera were engaged in the cavity of the tunic, and thus without touching the ring the parts were easily restored. In no case have I observed a protrusion of the tunica vaginalis becoming engaged in the hernial sac.

As the hydrocele may be covered wholly or in part by a hernial sac, containing a greater or less portion of the epiploon, when puncture is performed we must take care neither to wound the sac nor the testicle. The relations of the two sacs merit your attention; they are far from being invariable. In some cases, though the hydrocele forms the hinder and lower portion of the mass, the watery tumor is often situated in front and outside of the hernia. In other cases the tunica vaginalis penetrates the hydrocele, and constitutes a true watery hernia in its cavity. The contrary likewise may occur, and then the tunic is seen to yield in some of its points corresponding with the hernia, and a laceration is formed through which some of its parts protrude. It happens also sometimes, that the hardness and elasticity, and the tightness, of the margins of this laceration are such, that the parts forming the rupture are irritated, bruised, locked in the passage; strangulation presently ensues, and it is commonly, though erroneously, attributed to the constriction of the ring.

Among other complications of hydrocele I shall merely mention sarcocele, a memorable case of which is stated in the first volume of our *Leçons Orales*. But I must call your attention for a few moments to several cases less frequent and less known. Serous cysts may be developed in one of the bursæ, to which they may give a considerable volume. In such cases a scirrhous degenerescence of the testicle has been thought of, and the part has been extirpated. Again, those cysts occasionally show themselves in the body of the organ itself. This is what Morgagni calls hydatids of the testicle; and it is to the rupture of those cysts that he attributes the formation of the hydrocele. It is needless, in the present state of science, to discuss the value of this opinion; we shall only observe, that a hydatid cyst developed in the thickness of the cord, or in that of one of the bursæ, may by its softness, elasticity, its greater or less transparency, and the other characteristics which it displays, very readily induce us to fancy the presence of a hydrocele of the cord, or of the tunica vaginalis; particularly in the case of hydroceles whose cavity is divided into cells, it is very easy to fall into the mistake. I have seen several individuals of one fa-

mily affected with this singular disorder. I treated them by incision of the cyst, and they all got well.

Cysts containing purulent or honey-like matter, serofulous testicles, and other products of chronic inflammation of the testicle, which have been sometimes called encysted hydrocele of that organ, constitute alterations very different from that which we have just now noticed. These purulent or other deposits require either excision of their parieties, or extirpation of the organ in which they are.

The tunica vaginalis occasionally presents degrees of disorganization, which it is worth your while to study carefully. At the commencement it is thin, transparent, and easy to be moved; at a later period, when the affection is of some standing, this envelope, or rather the cellular tissue of its external surface, frequently acquires a great thickness, and a hardness approaching that of cartilage. Transparency is then generally at an end; and after puncture, the tunic, instead of sinking, remains as a true shell around the organ. I have sometimes seen this serous layer become the seat of sanguineous transudations, or present osseous plates of more or less extent. The following cases will give you a good idea of this sort of condition, and the kind of difficulties you will sometimes meet in practice.

CASE V.—*Cartilaginous hardening of the Tunica Vaginalis.*

An old man in 1815 came to the Hôtel Dieu, with a scrotum larger than the two closed fists. In front it presented a manifest fluctuation, and behind two hard tubercles. It was considered to be a hydrocele, or a hydro-sarcocoele. The man died in a state of great debility, and his body was examined. Beneath the skin and the dartos muscle was found a fibrous membrane, rather dense in its structure, covering a cartilaginous membrane, which was no other than the tunica vaginalis; it was cut into with precaution, when a large quantity of liquid, of the colour of wine lees, flowed out, leaving behind it a substance of the same colour, but without consistence or cohesion: this was decomposed blood. Upon dividing the cartilaginous membrane in different directions, the testicle was at last found, converted into a thin flattened mass, lying against the membrane. The two tubercles were formed by a circumscribed thickening of the cartilage, which had become osseous at the centre.

CASE VI.—*Apparent Sarcocoele—Removal of a sound Testicle.*

M. D., of St Domingo, a man of colour,

aged about 40, having bruised his right testicle violently, felt in it for several years the severest pains, and found it increasing in volume. He determined to come to Paris. Upon his arrival the testicle was hard, heavy, irregular, and besides being habitually in a state of exquisite sensibility, it was from time to time the seat of lancinating pains, which are usually regarded as symptomatic of carcinomatous degenerescence. M. Dupuytren announced the presence of a sarcocoele, and advised extirpation, which was presently performed. For greater certainty, the operator, after stripping the organ by incision, plunged his knife into a fluctuating point which he observed on the surface, and from which there flowed at once, and in a jet, a reddish inodorous liquid, like that peculiar to the cells of degenerating tumors. There was no longer any doubt about the case, and the extirpation was completed. Upon examining the tumor, it was found to be almost wholly formed of the tunica vaginalis, which had become cartilaginous, and irregular in its density; that the cavity which had been punctured was no other than its proper cavity, and that the fluid which came away was the product of a mixture of blood, which came from a round regular opening, about two lines in diameter, passing through at once the tunica vaginalis and the albugineous membrane. Through this opening the testicle was perceived in a perfectly sound state; so much so, that there was every reason to be sorry for the course that had been adopted, through an ignorance of the true nature of the case.

Method and material for injection.

The radical cure of hydrocele is usually effected by injection. I have, however, been successful in obtaining an equally beneficial result by the use of vesications applied over the scrotum. An irritation is thus produced, which is propagated to the tunica vaginalis, determining absorption of the liquid which it contains, and reciprocal adhesion of the opposite surfaces. The material which I have found best for injection is the following:—In a pint of Roussillon I boil two ounces of roses of Provins, and add to the strength of the decoction by a few tea-spoonfuls of brandy. I make three successive injections, at intervals of three minutes each; and a precaution which I always deem it proper to take, is, to be sure, before each injection, that the extremity of the canula has not slipped from the cavity of the tunica vaginalis. Through neglect of this simple precaution, the scrotum has been sometimes so much injured as to suffer eventually from gangrene.

FINANCES OF THE COLLEGE OF
PHYSICIANS.

IN obedience to the order of the House of Commons, the Royal College of Physicians have made the following return*, which contains an account of the money which has been received by them, from persons admitted as Licentiates, from 1st January, 1823, to 31st December, 1832; and also an account of the manner in which it has been appropriated. In explanation of this return, from which it appears that the annual expenditure of the College considerably exceeds its revenue, they beg to state, for the information of the House of Commons, that in addition to the sums of money mentioned in the following return, the whole income of the College arises from various sources—viz. first, from fees paid by Fellows, who each pay on admission 95*l.* 4*s.*, a sum including 40*l.* for stamps; secondly, from money paid by Extra-Licentiates, each of whom pays, for Letters Testimonial, 17*l.* 9*s.*; and, thirdly, from rents of lands and houses, the donation of former Fellows of their Society.

But for the last four years, the whole income of the College has not equalled its expenditure; the first amounting to 4115*l.* 16*s.* 5*d.*; while its expenditure has amounted to 4821*l.* 12*s.* during the same period.

Further, they beg to state, that, with the exception of a lease of the ground upon which the building now stands, the College has never received any pecuniary aid from the Crown since its foundation. The original building for the meetings of the Corporation was purchased and added to by the private subscriptions of the Fellows of that time; and when this was burnt down at the great fire of London, the edifice in Warwick-lane was built at the cost of the Fellows; and the funds for the erection of the present building in Pall-Mall East, which cost 25,000*l.*, were raised from the sale of the premises in Warwick-lane, which yielded 9000*l.*; from 2000*l.* given by the Trustees of Dr. Radcliffe; and from the subscriptions of the present Fellows.

To meet these great demands, the College has foregone every expense, except such as was absolutely necessary to promote the legitimate objects of its institution, to further which the Fellows still continue a small annual subscription.

* It appears that, between the years 1823 and 1832, 117 licenses were granted; which, at 24*l.* 15*s.* each, yields 2895*l.* 15*s.* We do not think it necessary to insert the return at length.—E.G.

CANINE MONSTROSITY.

MR. ATKINSON, of Romney Terrace, Westminster, who not long ago communicated to this journal the particulars of a case of feline monstrosity, has since met with an example of a dog without a nose, and having only one eye. They are both in his possession, and may be examined by any person curious in such subjects.

Prevailing wind N.W.

A heavy shower of rain, accompanied by two peals of thunder, in the afternoon of the 10th; otherwise generally clear.

Rain fallen, .05 of an inch.

CHARLES HENRY ADAMS.

LITERARY INTELLIGENCE.

Preparing for publication, a New Exposition of the Functions of the Nerves, by James William Earle, Esq.

Dr. Ayre, of Hull, has in the press, a work on the Nature and Origin of the Malignant Cholera, and on the Treatment of it by small and frequently-repeated Doses of Calomel.

Dr. Burne is preparing for the press, a Treatise on the Causes and Consequences of Constipated Bowels.

DISEASES OF THE STOMACH AND
BOWELS.

WORMS.

It has been said that nature has provided every animal with other animals to prey upon it, to make a habitation of it, and derive food from it. It is even said that a flea has its flea, and if so, I suppose this would have its flea's flea. How far this matter goes, it is impossible for me to say.

Divisions.—However, some of these animals evidently come from without, and exist but temporarily perhaps, and these are called *ecto-zoa*; whereas those that colonize, establish themselves, breed a posterity, and become whole families at last, are termed *ento-zoa*.

Ecto-zoa.—As instances of the *ecto-zoa*, those which reside upon the skin, I may mention fleas, lice, bugs, and other delicate little animals. But we have also others which reside within, some getting into the anus, some into the maxillary sinuses, some into the stomach and intestines, some into the biliary ducts, some also getting into the cellular membrane beneath the skin. I had a patient, an infant, who discharged about a dozen live larvæ, maggots of the common fly. The child had suffered a chronic cough, but as soon as these dozen larvæ were discharged from the intestines all alive, it lost the cough. I saw them myself in the napkin, moving about in the feces,

exactly as you might have seen them if they had never been in the body. I understood that it had eaten part of a high pheasant some months before. I have had two cases in which a live caterpillar was discharged from the intestines. One of these cases occurred in a woman who was in the habit of eating cabbage stalks when she washed them for dinner. The moth lays its eggs on cabbage stalks, and no doubt this patient had swallowed some of the eggs, and it so happened that one of them was hatched. Dr. Good, in his work on Medicine, gives an instance of a flesh fly, the *musca cibaria*, or rather the larva of it, being discharged by means of purgatives, after producing considerable derangement. The larva of the bee, and even live spiders, have been discharged from the alimentary canal downwards, by human beings. Even the *triton palustris* and the *lacerta aquatica*, the domestic and the horse leech, have been discharged by vomiting, and have been found in the stomach. Leeches, when they get into the stomach, from sucking the blood will sometimes attain so large a size as scarcely to be recognized. When soldiers have been encamped on marshy ground it has been found dangerous for them to go to sleep, lest leeches should get into their mouth and destroy them. Life has been lost from leeches crawling down the œsophagus, sucking the stomach, and producing fatal hæmorrhage. I once saw two centipedes, said to have been vomited by a girl twelve years of age. There was no reason to suppose that any deception was practised, but she vomited them, and the vomiting was attended by a tightness in the throat. The animals had lived three days when I saw them. The mother said the girl had vomited a black beetle two months previously. She had palpitation of the heart and pain, and heaviness of the head. Dr. Duncan, in the ninth volume of his Medical Commentaries, mentions the case of a boy who discharged four caterpillars after

a dose of calomel. It is said that several crawled out at the anus afterwards, and on exhibiting calomel and jalap an incredible number came away. I should not have paid much attention to these accounts if I had not myself witnessed similar effects. The boy mentioned by Dr. Duncan likewise discharged a lumbricus. I have no doubt that some persons are the sport of these insects; in others they would die. It was ascertained in Dr. Duncan's case that the boy had frequently gone into the garden and eaten a young cabbage leaf, just as I ascertained that the woman ate cabbage stalks when preparing them for dinner. In Hufeland's Journal for 1822 there is an instance of live and dead slugs being discharged by vomiting and purging. I recollect a case in the MEDICAL GAZETTE, mentioned by Dr. Alderson, of Hull, of a centipes being discharged from the stomach, exactly as occurred in the case that I saw. You know that horses have what are called *bots* in the stomach, if they swallow the eggs of the common gad fly. The gad fly lays its eggs upon their coat, they lick their coat, and swallow the eggs, which attach to the splenic portion of the stomach at a certain period of the year. I suppose all this is natural, for I believe they are often found in the stomach of horses. Nature appears to have destined this place for their reception. When they are mature, they escape through the intestines, and become gad flies. Those which evidently come from without are all called *ecto-zoa*.

You will hear numerous instances of severe headaches having arisen from insects getting into the nostrils and crawling into the sinuses, and also from their getting into the meatus auditorium. Nothing is more tormenting, I understand, than a flea in the ear. If it get into the ear it buzzes about and makes as much disturbance as a giant would; but this state may be cured in a moment. I recollect the case of a patient of my own who had been in the greatest agony from this circumstance, but on pouring a tea-spoonful of oil into the ear it was quiet in a moment. I suppose it was suffocated.

There is a kind of gad-fly which settles in the rectum, and it is therefore called *æstrus hæmorrhoidalis*: it has been found to make its way even into the womb. There is one kind called *æstrus ovis*, from its always selecting sheep. The guinea worm comes from without, perforates the skin, lies for a considerable period in the cellular membrane under the skin, and is the source of very troublesome ulcers.

Ento-zoa.—As to those which settle regularly in the human body, colonize, and descend from generation to generation of human beings, they are found both in

cavities and in the substance of the body, and each of these *ento-zoa* has its particular habitation. The one called *lumbricus* always occupies the intestines or stomach; the one called *strongyle* particularly fixes on the uterine organs; the one called fluke is found in the liver, and the filaria, or guinea worm, is found in the cellular membrane.

There are three chief forms of these animals found in the living body; one set are round, in cylinders or spindles; another set are flattened like bobbin, and the third set are globular or vesicular. It is the latter that are chiefly found in the substance of organs.

Arrangements of various authors.—Linnæus arranged them according to their situation, accordingly as they were found in the intestines or in other viscera. Rudolphi, the naturalist, of Berlin, names them from their form, and makes them into five classes, the first of which he terms *nematoides*; then he has a second class, which he calls *acanthocephala*. These are animals which are of the hydatid kind; they have no spinal canal, but distinct genital organs. There are two sexes, and they are found only, or chiefly, in the intestines of swine.

Then he has a third class, which is called *trematoda*. These are flat, with minute pores. It is said that these have no intestinal canal, but distinct genital organs.

Then the fourth is *cestoides*, which is the tænia, or flat worm, and the fifth he calls *cystica*. These are hydatids.

Cuvier makes more simple classes than these: he arranges, in classes, those which have a distinct digestive cavity, and those which have no distinct digestive cavity to be traced to the interior: the one is called *cavitaires*, because it has a digestive cavity, its regular canals and an anus; and the other *parenchymateux*, because it has nothing but a uniform structure, with no regular digestive tubes. This last class embraces all the classes of Rudolphi except the first; and those which have a regular digestive apparatus comprehend the round worm, the little ascarides, the strongyle, and the guinea worm, and therefore instead of the five kinds of Rudolphi, Cuvier makes but four.

I will now begin with the *cavitaires*, or, according to Rudolphi, the *neomatoïdes*.

ASCARIS LUMBRICOIDES.—Formerly these were termed lumbrici; but from their analogy to the ascaris, they are now called *ascaris lumbricoides*. This worm has external integuments; it has muscles, a digestive apparatus, a genital apparatus, and some have thought that it has a circulating and nervous system. The muscles of this worm lie immediately under the skin; the fibres are two-fold, both long and transverse;

the digestive organs are quite straight; it has a triangular mouth, with three tubercles; the anus is at the opposite end, and the genitals fill a great part of the animal. Each sex is a different individual; and the opening of the genitals is near the anus. You will find it from twelve to fifteen inches in length; it is of a yellow colour; and as many as eighty of them have been discharged from one individual. The celebrated Professor Frank mentions a case in which the intestines were absolutely crammed.

Situation.—This worm is usually found in the small intestines, occasionally in the large ones, in the stomach, in the œsophagus, the pharynx, or mouth (I have known a person vomit one); but its proper habitation appears to be the small intestines. Andral says that he found a lumbricus in the pharynx. It got out of the small intestines into the stomach, from the stomach into the pharynx, and one end turned down into the larynx and there caused sudden death, having suffocated the patient. Andral also saw several in the liver, apparently having crept up the ductus choledocus communis to the duodenum. Dr. Baron, of Gloucester, mentions seeing a lumbricus in the ducts of the liver; and an old physician, who wrote on morbid anatomy, mentions seeing several worms in that situation. Andral says that he saw a liver absolutely perforated with them; and sometimes they have perforated the intestines and got into the peritoneum. They have sometimes been known to escape externally through the integuments, or into the urinary bladder, or into the vagina.

Difference between it and the common earth worm.—You will observe, of course, the resemblance of this to the earth worm; but the earth worm is found to be less pointed; its mouth is only a small slit at the under part of a rounded head; and the anus is not near the extremity, but at the very extremity. The earth worm is more fleshy, more marked with rugæ, and it has one most distinguishing circumstance, a quadrangular row of processes like feet, which it can erect and move about; it has also three longitudinal lines at the upper surface, and it is an hermaphrodite. The ascaris lumbricoides is far most common in children, and rarer as people grow old.

TRICOCEPHALUS.—The next worm in point of size is that formerly called *tricuris*, three-tailed; but unluckily our predecessors took the tail for the head, and it is now called *tricocephalus*. It is a very small worm, about one inch and a half, or two inches, in length; it is of a violet colour, and the anterior end is much finer than the posterior; it becomes a mere point for the mouth. The posterior end of the male is bent, and it has a straight alimentary

canal, around which are placed the organs of generation.

Situation.—This is found lower down than the last; it occurs chiefly in the cæcum, and there are generally several of them. It is much more common in infants than in others.

OXYURIS.—Another worm which has also an alimentary canal, is the ascaris, or more properly speaking, the *oxyuris*, or drop-tail. This passes with the common people under the name of thread worm. It lives as low down as it possibly can in the rectum, and frequently makes its exit; and when it once gets out, it cannot get back, but shrinks up and perishes. It is far shorter than the others. The male is said to be about a line and a half in length; the female four lines. The organization is the same as in the other two kinds. It is not only usually found in the rectum, but it is generally surrounded by mucus. They will crawl out, and old women sometimes amuse themselves by seeing how many they can catch in a night, in order that they may shew their exploits to the doctor in the morning. I have known them crawl out of old persons, so that they complain that they have picked them off their thighs in bed.

The other description, which are called *parenchymateux* by Cuvier, have no digestive or other perceptible organs, except instruments of locomotion. They have various forms; some are spheroidal, some flat, and some long. They are the *acanthocephala*, that with two points; the *trematodes*, that with a perforation; the *cestoides*; and likewise that of which I am now going to speak, *tania*. These are found in the substance of the body, and in various cavities; and those which are called hydatids, *cystica*, and which are continually found in the substance, but occasionally in cavities; and sometimes they have a particular cyst.

TENIA.—I will now proceed to that which we meet with every day in the living subject, and which is called *tania*. This is never less than several feet in length, and sometimes many yards. One author mentions one measuring 150 feet, and another foreign writer saw one 300 feet. Though I never saw one so large as that, yet I have frequently seen seven, eight, or ten yards, come away at once. It is fine, and has a series of articulations, each with natural pores. Dr. Baillie says that the last joint has an aperture. The anterior part of the worm is very fine; the head is square; and it has little retractile hooks. There is no regular organization within—that is to say, there is nothing leading to a digestive tube. It is almost a mere amorphous mass; yet you may feel arborescent vessels about the joints, and a serpentine canal is sometimes

seen at the edges. It moves in an undulatory manner.

There are two kinds seen, the one called *tænia solium*, or armed *tænia*, and the other *T. lata*.

That which is called *T. solium* is about the third of a line broad towards the head, and has crotchets before, and on each side the articulations. The other, which is called *T. lata*, is shorter and broader, and has no crotchets. The latter usually exists in cavities, three or four in an individual, and from twelve to fifteen feet long.

The tape worm is far more frequent in adults than in children, and in the dog than in the human subject; but it is said that in the dog, and in other brutes, it differs somewhat from that observed in the human subject. It is more common in some countries than in others. In Switzerland, the water is very bad, and the *tænia solium* is very common there: the *T. lata* is not so common.

Entozoa probably were originally Ectozoa.—Now, as to these worms, it is probable that a great number of those which I have now been speaking of as entozoa, really came originally from without. Many persons on going to particular parts, have presently become subject to worms, just like other people in that particular neighbourhood. Persons who by accident have drank bad water, have frequently from that time most decidedly had worms. There can be no doubt that *tænia* may be continually traced to external sources; and with respect to ascarides, you will see a remarkable case published in the Dublin Transactions, vol. ii. where a whole family was infested with this worm, and every servant who came to the house, after a certain time, had it. Although medicines were taken, yet nothing liberated these persons from it: and at last ascarides, very similar, only a little browner, were discovered in a well, from which the people derived all their water. The family had resided there many years, but they now found it necessary to change their habitation, and from that time nearly all of them lost their worms. The race was kept up in one individual, but the greater part of the family lost them on ceasing to drink that water. In regard to *tænia*, Dr. Darwin mentions that the fens of Lincolnshire are famed for them. Sir John Pringle says, that the lumbrici are very common in the remittent fevers of marshy countries, and when they have been once introduced, it is impossible to say how long they may remain: they may continue for many years. It appears to be a fact, that they may be transmitted from generation to generation. A German writer of authority says, that he actually

found worms in the intestines of a fœtus. This is not at all surprising, because the germs may be easily transmitted from the mother to the off-spring. Lamarek, the French naturalist, has found the same thing. *Tænia* have been seen in a muddy spring, only rather smaller than those observed in human beings. You know that the lower animals are easily altered by particular circumstances, and therefore it is not surprising that ascarides should be of a different colour and size in the body and out of it—in wells and in the living subject. I recollect being told by a friend, who had travelled a great deal in Syria, that he drank some bad water, and was exceedingly ill. He did not know what was the matter with him for a week or so, when all at once, after taking a good dose of calomel, he discharged little more than a heap of small maggots. What they were he was not naturalist enough to inform me, but he got well, and his illness could be traced to this external circumstance. The *tænia* may come from without, and so it would appear may the ascarides, and in all probability the worm called *ascaris lumbricoides*.

Debility favourable to the increase of Worms.—Generally speaking, these worms prevail more especially in proportion as the patient is weak. You are aware that persons who are exhausted from fever, will become the subjects of vermin. In extreme debility of the constitution, you may have a patient cleaned several times a day, and be covered with a fresh crop of vermin. So it is, in general, within; the more weakness there is of the body, the more the entozoa thrive. Bad air, bad food, and the want of sun, will contribute to their appearance. I formerly mentioned, that when rabbits were kept in a bad place, they would become subject to hydatids. Sheep, in wet pastures, also, become subject to these animals.

Spontaneous Cessation.—There can be no doubt that children are much more disposed to ascarides and to lumbrici than others; and not only so, but as age advances, the constitution frequently becomes so unfit for the continuance of these worms, that they are absolutely shaken off without any physic at all. There can be no question, at least there is none in my mind, that children cease to become the prey of worms. Thousands have ascarides when they are young, and never have them afterwards. This is not so common an occurrence in regard to lumbrici as ascarides, but the remark is correct there to a certain extent. The early period of life seems to favour these animals; why, I do not know, but such is the fact. You will see some of these worms in persons of the highest

health: you will see persons with a good colour complaining of worms, and they will be able to verify their assertion.

Symptoms.—With regard to the symptoms, worms sometimes produce the most distressing effects, so as to make life a burden; and at other times, they produce no symptoms at all, and a person only knows that he has worms, because he discharges them. I have seen many individuals, who, to their great astonishment, discharged several feet of tape worm, not having the least idea previously that there was any thing the matter with them.

When worms exist in the alimentary canal, the symptoms usually are (I will begin with the head and go downwards, for the sake of assisting the memory) headache—sometimes it is sharp headache, sometimes it is dull, and frequently there is a stabbing of the temples; heaviness, giddiness, even convulsions; perhaps regular epilepsy: some authors mention even tetanus—depression of spirits. There is a black circle around the eyes; paleness of the face; more or less tumidness of the upper lip; great itching of the nose; foulness of the tongue; thirst; offensiveness of the breath; palpitation; shortness of breath; cough, and even hæmoptysis. Then, below the diaphragm, anorexia—or excessive appetite; nausea; vomiting; a gnawing pain at the scrobiculus cordis; pain perhaps all over the abdomen, or in various parts of it; pricking pain, too, in the abdomen—even tenderness of it; griping; purging; itching of the fundament and of the genitals; a discharge of mucus from the rectum; feverishness, and emaciation. These are the symptoms which worms produce, but of course you do not see all these in every case. On the other hand, worms will exist in the alimentary canal without giving rise to any symptoms whatever.

Expulsion.—As to getting rid of worms, in the first place any brisk purgative may answer the purpose. A good dose of calomel and jalap is an old remedy, and a very excellent one. Sir John Pringle used to give twelve grains of calomel and half a drachm of rhubarb. Some give gamboge, but I do not know its specific power; it produces nausea, and is not so good as calomel and jalap.

Destruction.—But besides these remedies for the expulsion of worms, we employ others for the purpose of destruction; and one of the best is unquestionably oil of turpentine. In the case of ascarides, which are easily know from their crawling out, from their appearing in the stools, and from the extreme itching which they cause in the rectum, it is best to give the oil of turpentine by injection. You thus send it immediately on the parts where the worms

reside, you save the patient the trouble of a filthy dose, and you save the stomach from great disturbance. From a drachm to half an ounce may be given to a child, mixed with gruel, and it will often bring away thousands. Adults will take a larger dose in an injection—an ounce or more; but perhaps a very large dose is not so well. It causes so much irritation that it may produce an immediate expulsion; it may not lie long enough to kill the worms, but they may be discharged by the intestines.

In case of other worms, the oil of turpentine should be given by the mouth; and the dose then is from half an ounce to three ounces. It is best not to give it fasting, lest it should create sickness and be lost. Patients had better take it a couple of hours after some meal, and remain perfectly quiet, lest vomiting be induced. It may be taken pure, the same as a glass of spirits, or in gruel or any thing else which the patient chooses. In females, half an ounce is generally a proper dose to begin with, and it is seldom right to give more than an ounce; but in men, if they be not particularly delicate, it may be right to give two ounces. The effect it generally produces is that of making the patient sick, purging him violently, making him giddy, and causing extreme vertigo. These will all go off, but occasionally it will not purge itself away, and therefore it is best to give a dose of castor-oil, and repeat it every hour or two till the medicine passes freely. It rarely affects the urinary organs, but sometimes it does. Now and then you will have bloody urine from it, a frequent desire to make water, and great pain; but in general these effects do not occur, and when they do there is usually an idiosyncrasy, and they will occur from the smallest doses. Large doses usually work themselves off; but where they do not, I have seen these effects. Where the remedy does not produce irritation it has been absorbed, and the urine has smelt strongly of it for several days. I conclude that where it produces violent symptoms there is a little idiosyncrasy.

The history of our knowledge of this medicine is rather curious. So far as I have read, it appears that its use in worms was first mentioned in 1792, by a general practitioner, at Putney, of the name of Madden. A man had been long accustomed to pass tape-worm, and a friend advised him to take oil of turpentine. He took two drachms, and to his great astonishment discharged five yards of tape-worm and several pieces afterwards. At the time Mr. Madden wrote, which was three years and a half afterwards, he was quite well. This fact was lost sight of, not in the least attended to, till a paper was published, in 1811, in the *Medico-*

Chirurgical Transactions, by a physician at Durham, giving an account of a sailor. He had been in the habit of taking gin to expel a tania; but at last it failed, and he took a glass of oil of turpentine, thinking that that was stronger. It was quite successful. What is very curious, after this paper was written, in 1817 some other person published a paper in the Transactions of the London Medical Society, where Mr. Madden's account was contained, and claimed the discovery of the remedy. The circumstance was forgotten, and the Society allowed the second paper to be published. It is one of the best remedies that we have; it will expel all sorts of worms—ascarides, lumbrici, tania, and all others. Of course occasionally it will fail; but you should give it in large doses, and take care that it finds its way out. You should follow it up with a dose of castor-oil every two hours, otherwise the patient may be brought into some danger. I have seen a degree of danger produced in a child, from inflammation of the intestines coming on, but it went away in a few hours.

Before concluding the subject of *ectozoa* and *entozoa*, I should state that we are not quite certain with regard to some of these, whether they deserve the name *ectozoa* or *entozoa*. Those that reside within, breed within: *entozoa* have particular residences. Some invade the alimentary canal generally, and others reside in particular parts of the canal.

The same thing has been observed with respect to those which reside on the surface. Whether they have an external origin or not, we are not quite certain. Then, again, there are some vermin, small lice, which live only in the head, and it is said that they will not thrive any where else. There are others which live only on the body; and it is said, that if you put them into the hair of the head, they die. These have been vulgarly named *crab lice*, but scientifically they are called *pediculi pubis*. They thrive only on the pubis.

Chiggers.—I should mention that there is a particular kind of flea, very large, a sort of giant, which passes under the name of *chiggre*. This is found particularly among the negroes, and is a source of great trouble to them; for it is so powerful, that it gets under the skin, and there burrows, and forms a bag, in which it lays its eggs, the result of which is a very troublesome ulcer. I had a patient at St. Thomas's Hospital, a year or two ago, who had lost the nail and the extremity of each great toe through chiggers. There was a cicatrix running across the toe, which had been occasioned by this animal. The negroes are very expert at taking them out, in whomsoever they occur. The

great point is to remove the bag entirely; for if any part remain, an oozing occurs, and no good is done. There is a story told of a person who was anxious to have it put to the test, whether chiggers were a particular sort of flea, or only a variety of the common kind, and he therefore let one which had got under the skin go on burrowing, in order that he might observe their increase and habits. The consequence was not only a troublesome ulcer, but mortification. A gentleman who has been much in the West Indies is of opinion (I do not know whether he has any real ground for it) that that kind of elephantiasis which is called *Barbadoes leg*, in which the skin becomes exceedingly hypertrophied, and that disease of the scrotum in which the skin and the subjacent cellular membrane are excessively hypertrophied (just such a case as occurred in the Chinese at Guy's Hospital), all arise from chiggers. Whether he is right in his opinion, I will not pretend to say; but he is a man of very careful observation.

Other Remedies.—The oil of turpentine has been particularly used in the case of tapeworm in the intestines; but it is equally good in the case of other kinds of worms.

The *dolichos pruriens*, or cow itch, has been used particularly against the lumbrici; and the best account I can give you of that remedy is to be found in a work by a general practitioner of the name of Chamberlain, which was written some years ago. The pubes of the *dolichos*, the small spiculæ, are scraped off, and made into an electuary, and the electuary may be given in almost any quantity. I have found the oil of turpentine so efficacious, that I have not had much recourse to cow itch; but Mr. Chamberlain mentions that you may give a large quantity of it. A woman at St. Thomas's Hospital took a drachm of the pubes of *dolichos* twice a day, for five days, and afterwards a purgative was given to her. The proper mode of exhibiting it is in an electuary, made of senna or treacle. As good a mode of exhibiting it as you can adopt is to thicken it to a proper consistency with treacle, and let the patient take a tea-spoonful of it two or three times a day. You should occasionally give a purgative. It appears to do no harm: the only inconvenience which my patient experienced was a tingling in the mouth; but when it had once got into the alimentary canal, no further unpleasant symptom arose. The bark of pomegranate root has also been particularly recommended. Half a drachm may be given every half hour till vertigo is produced. You will find a good account of this in the 11th volume of the *Medico-Chirurgical Transactions*. It has the effect of produc-

ing giddiness, sickness, convulsions, pain in the head, and purging. There is no rule of course for the quantity that will produce this, and therefore it is well to give half a drachm of the bark powdered every half hour in some water, till the patient begins to feel sickness, or it purges him. It is for the tenia that this is particularly recommended, and there can be no doubt at all of its virtue. These are the only things with which I am practically acquainted. Steel filings have been mentioned, and a woman once took an ounce and a half in a day, which was purged off with a cathartic, but without any sensible effect whatever.

You will find in books on *materia medica*, a number of medicines recommended. The bark and shoots of the bastard cabbage-tree and fern have been particularly spoken of as a remedy for tenia. Indian pink, which is an acrid narcotic, has undoubtedly been useful. You will find a curious case in the second volume of the Transactions of the College of Physicians of a man who took two pounds of common salt in four pints of water, and by that means got rid of an immense number of ascarides. It is well known that salt is rather a preservative against worms. The flukes which are found in sheep come, it would appear, from stagnant water; and it is said, that by giving the sheep plenty of salt, you may prevent them from becoming the victims of fluke.

Electricity has been employed, the passing of shocks through the abdomen, and now and then a worm has come away: it has been rendered uneasy, and has endeavoured to escape.

But besides those means which are necessary to expel the worms, it is of the highest importance to restore the health. There can be no doubt that worms derange the health, and if you can get rid of them, health will return; but they are frequently present on account of bad health, and therefore it is necessary to expel them by common purgatives, which often answer very well; but at the same time you must endeavour by all the means in your power to restore the health; to take care that the patient has wholesome food; and to put the digestive organs into the best order you can. If this be done, you will frequently find worms disappear without any other means being employed.

Spontaneous Cessation.—Without giving any purgative medicines whatever—without doing any thing to expel or destroy worms, you will find in a great number of cases where children have become their prey, they will spontaneously cease. Children are far more subject to ascarides and lumbrici than adults, and a great number of children have them at a particular

time; but as puberty arrives, the constitution is less favourable as a habitation for worms, and they cease spontaneously. Most of us have been freed from worms spontaneously, although they may have been a great torment to us at the younger period of life.

STRONGYLE.—One kind of worm, you will recollect I mentioned, was found in the bladder, and this is called the *strongyle*. Dr. Davis, of this University, once shewed me a phial, containing a large number of them, all creeping about in full animation, which came from a lady's bladder: she had discharged a large quantity of them for a considerable time. Mr. Lawrence has described a curious case of this description in one of the volumes of the *Medico-Chirurgical Transactions*, in which from 800 to 1000 of these worms were discharged from the bladder in about a year. Some of these were an inch in length. They were very hard and firm. These worms cause great irritation, a frequent desire to make water, and sometimes bloody urine. In the fifth volume of the *Medical Essays*, which is a very excellent work, there is an instance of one an inch in length, and as broad as the smallest part of a needle. It was discharged after having produced bloody urine for many years. What could be done in a case of this description I do not know. Whether turpentine given by the mouth would answer, is doubtful: it would find its way to the urinary organs, because it impregnates the urine, but whether in sufficient quantity to destroy the worm, I do not know. Whether it would be right to inject the bladder I cannot tell; but first I should try an injection of olive oil, just as I should kill a flea in the ear. Whether these worms are formed in the bladder, or come from the kidneys, I do not know: the point is not yet determined.

These are all the observations that I have to make upon the abdomen properly so called. I shall next treat of diseases of the urinary organs, commencing with inflammation of the kidney.

ON THE NATURE OF SLEEP.

By A. P. W. PHILIP, M.D. F.R.S.L. & E. &c.

Read before the Royal Society, March 7, 1833.

THERE is no question relating to the living animal which involves a more general view of its phenomena than the nature of sleep, and, probably for this reason, none respecting which opinions are more vague

and unsatisfactory. I propose to review these various phenomena, for the purpose of ascertaining the organs in which its immediate cause exists, the laws on which it depends, and the effects it has on those parts of the system which are not concerned in its production.

We can perceive no final cause of the alternation of watchfulness and sleep, but such as has its origin in the imperfection of our nature. The end of life is enjoyment; and as sleep, if we may not regard it as a positive evil, prevents uniformity in the accomplishment of this end, to say nothing of the occasional inconveniences which attend it, were we as well acquainted with the principles of the animal, as we are with those of the solar system, we should probably find that this defect is, in the nature of things, as unavoidable, as the recurrence of darkness and a degree of cold which benumbs, and of heat which overpowers our faculties.

We shall never, perhaps, be able to tell why certain organs are capable of constantly maintaining their functions, while others require intervals of repose; but it is not difficult to perceive the necessity of the former part of the arrangement, because the permanent functions are those on which the life of the animal immediately depends, the intervals of repose belonging to those alone which are the means of intercourse with the world that surrounds him, and which therefore have no direct tendency to destroy life.

In tracing the relation of the nervous and muscular systems in the last paper I presented to the Society, I had occasion to recal to their recollection the different relations which the muscles of voluntary and involuntary motion bear to the nervous system, and to point out that the two sets of nerves, which form the medium of connexion between the active parts of that system, and these classes of muscles, obey different laws; the one conveying the influence of only certain parts of the brain and spinal marrow, the other conveying and combining that of the whole of these organs. The former, it is now to be observed, while they are associated, on the one hand, with the organs of sense and the muscles of voluntary motion, are associated, on the other, with those parts of the brain and spinal marrow on which the mental functions depend*; the latter, namely, the nerves which arise, as far as we can ascertain by experiment, from all parts of those organs, being associated, on the one hand, with all those parts, and on

the other, with the muscles of involuntary motion and the organs on which life immediately depends.

Thus we find in the more perfect animals two systems in a great degree distinct from each other; the former may be termed the sensitive system, that by which they perceive and act, and consequently are connected with the external world; the latter the vital system, that by which their existence is maintained. To understand the nature of sleep, we must determine the properties peculiar to each of those systems which have relation to that state, and the manner in which each is capable of influencing the other.

When the reasoning powers are fatigued by continued attention, the feelings by the excitement of the passions, the eye by the exercise of sight, the ear by that of hearing, the muscles of voluntary motion by powerful and repeated contractions, &c. the organs of all these functions cease to be excited. In order again to excite them, either stronger stimulants must be employed, or they must be refreshed by repose, during which, the functions of life still continuing, their due degree of excitability is restored; and they thus again become sensible to the usual stimulants of life.

The operation of this law in the sensitive system may be observed under all degrees of excitement. We can perceive a very sensible effect from slighter degrees of exhaustion than that which produces sleep. After sleep there is a vigour which gradually declines till we sleep again; so that every degree of excitement is followed by its corresponding degree of exhaustion. This law of our frame is so prevalent, that physiologists have generally regarded it as belonging to every part of the system; but any degree of excitement which produces weariness, must, by a certain continuance of it, produce inability. It is evident, therefore, that were the organs of life to obey this law, a total failure of their functions must soon ensue. The sensitive system is restored, because the powers of life remain; but if these powers suffer a similar exhaustion, by what means can their restoration be effected? This consideration alone might have convinced physiologists that their excitement is regulated by other laws.

It is evident, indeed, that the circulation continues uninterruptedly, but this has been explained by supposing that the heart and vessels during the intervals of their contractions recover their excitability, the exhaustion of which, during each contraction, has been regarded as the cause of the relaxation which succeeds it.

This theory appeared to apply well to the heart, because during the intervals of its

* It has been shown experimentally in my Inquiry into the Laws of the Vital Functions, that the spinal marrow partakes of the sensorial functions. This is very little the case in man, but to a great degree in some animals.

contractions the stimulus which excites it is removed; but how does it apply to the vessels from which the stimulus is never removed, and which can support the motion of the blood, as has been ascertained by many experiments, independently of the heart*? An organ exhausted by the action of any stimulant will never recover its excitability under the operation of the same agent which has exhausted it. The retina will never recover under the same degree of light which has impaired its power, nor the nerve of the ear under the same degree of sound.

A very simple experiment, however, demonstrates that the theory is as erroneous with respect to the heart as the vessels. If in a newly-dead animal a ligature be thrown around the arteries attached to the heart, so that it continues gorged with blood, its contractions, although ineffectual, still continue to occur with the same regularity as before the ligature was applied. When salt is sprinkled on the muscles of the newly-dead animal, the effect is not permanent contraction succeeded by permanent relaxation, but a constant succession of contractions and relaxations, notwithstanding the continued application of the same stimulant, till their power is exhausted.

An experiment suggested by Dr. Wollaston, and with which he used to amuse his friends, strikingly illustrates the interrupted nature of muscular contraction, even where it is as nearly permanent as the nature of the muscle in its healthy state admits of†. If the elbows be made to rest on a table, and the end of a finger of each hand be pressed steadily on that part of the ear which covers the external passage, so as to press it down forcibly on the end of that passage, we hear a rapid succession of distinct concussions. This he ascribed to our thus being made sensible of the motion of the blood in the vessels. But did it proceed from this cause, the repetition of the concussions would correspond with the beats of the heart. That it arises from the rapid succession of the contractions of the muscles of the arm, by the action of which the end of the finger is pressed against the ear, may be proved by making the experiment in the following manner. Let the arms rest on the table in such a way as to press by their weight on the fingers which stop the ears, care being taken that the stopping of the ears be left to the weight of the arms, and in no degree produced by the action of the

muscles. When we succeed in this attempt, all sense of concussion immediately ceases. It will be found, that just in proportion as we succeed in preventing the action of the muscles, the noise abates, and when we perfectly succeed, ceases altogether. The same property of the muscle may be made perceptible to another of our senses. If a bird be allowed to rest on the finger, we perceive by the finger its weight alone; it so balances itself, that the continued action of its muscles becomes unnecessary. But if the finger be moved, so that the bird is obliged to cling to it to maintain its place, we perceive a thrill, which consists of the same rapid succession of concussions as in the former instance is perceived by the sense of hearing. The larger the bird is, they are of course the more distinct.

It is quite evident from all that has been said, that the state of the muscle is wholly different in the relaxation which intervenes between the contractions, from that which has supervened when the same stimulus can no longer excite it. Now it is not the first but the last of these states, which indicates any loss of power in the muscle.

The whole phenomena of the animal body demonstrate, that although it is true that a muscle may be exhausted by powerful and repeated contractions, it is not subject to the law which prevails in the sensitive system, that all degrees of excitement are followed by proportional exhaustion.

Thus it is that the muscles of voluntary motion often suffer exhaustion, because, being under dominion of the will, they are frequently exposed to excitement which is excessive either in its degree or duration, or both. Their exhaustion does not interfere with health, and for their restoration means are provided in the usual functions of the system. But the muscles employed in the vital functions obey a better-regulated stimulant, which never, except in disease, produces any degree of excitement that impairs their power. In many diseases we see the effect of such excitement. If it does not abate soon, and we cannot by artificial means in a short time reduce it, death is always the consequence; and even a short continuance of it produces a degree of debility that so impairs the powers of life, as to render their restoration both slow and difficult. Thus it is evident that on the capability of the muscular fibre to be moderately excited, without suffering any degree of exhaustion, life immediately depends.

This property belongs equally to the muscles of voluntary as those of involuntary motion, the exemption of the latter from exhaustion in the healthy state of

* Experimental Inquiry, Part II.

† We have reason to believe that in spasm the muscle is in a state of permanent contraction, probably the cause of the pain which attends this state.

the system not arising from any peculiarity in the nature of these muscles, but from the circumstances in which they are placed. In many diseases we find the muscles of voluntary motion in a state of excitement, that is, in a state of constant contraction and relaxation, which constitutes their state of excitement, during all our waking hours, that is, during all the time that those parts of the nervous system with which they are associated are capable of exciting them, without a sense of weariness or any other sign of exhaustion in them. The muscles of respiration, which are, in the strictest sense, muscles of voluntary motion*, are in a state of constantly renewed and gentle excitement during life. It is only in asthma and other cases, where their excessive action is required, that they experience any degree of exhaustion.

Thus the muscular fibre, in its laws of excitement, differs essentially from the other organs with which it is associated in the sensitive system. It is neither like them in the healthy state capable of uniform excitement, nor in it are all degrees of excitement followed by proportional exhaustion. But in the vital system, although all its other parts are capable of uniform excitement, the muscular fibre is not the only organ in which certain degrees of excitement are unattended by exhaustion. The same is true both of the ganglionic nerves and those organs of the brain and spinal marrow from which they derive their power, and which, it appears from direct experiment, are distributed throughout the whole extent of the brain and spinal marrow.

The secreting organs indeed, as well as those of circulation, are less vigorous in sleep than in our waking hours; but this, we shall find, besides that a diminished excitement cannot restore impaired excitability, but must, in proportion to its degree, still add to the exhaustion, is the necessary consequence of causes very different from their partaking of the exhaustion which prevails in the sensitive system. It is in disease alone that they suffer any degree of exhaustion, which in them produces a different species of debility, not an exhaustion analogous to that of the sensitive system; which it is even a means of preventing, by impeding the functions of life, and thus indirectly proving a cause of irritation to this system.

It appears from all that has been said, that in the sensitive system alone we find organs capable of exhaustion from all degrees of excitement, and the exhaustion of which is consistent with a state of health,

namely, the nerves of this system, and those parts of the brain and spinal marrow with which they are associated; but it is a necessary inference, from the facts stated in the last paper I had the honour to lay before the Society, that the former of these only obey the latter. To the latter alone, therefore, we must look for the exhaustion which is the immediate cause of sleep.

The parts of the brain and spinal marrow which are associated with the nerves and muscles of the sensitive system, gradually, from the effect of the usual stimulants of life, suffer such a degree of exhaustion that those stimulants can no longer excite them; and their functions, unless stronger stimulants be applied, necessarily cease. Impressions from external objects consequently are no longer perceived, and therefore cannot produce their usual effects either on mind or body. Thus the expenditure of excitability in those parts of the brain and spinal marrow, and consequently in the nerves and muscles whose functions depend on them, being arrested, the vital functions still continuing, such an accumulation of it takes place in all these organs as again renders them sensible to the usual stimulants of life, and the activity of the sensitive system is restored.

On the parts of the brain, and, in some animals, of the spinal marrow, as I have already had occasion to observe, which are associated with the nerves and muscles of the sensitive system, the mental functions depend. Hence the phenomena of dreaming, on which I shall make a few observations, immediately connected with the other parts of this paper, after considering the manner in which the vital is influenced by the state of the sensitive system in sleep.

We are now to consider the effects of sleep on those organs which have no share in its production.

One of the most important circumstances relating to the state of the sensitive system in sleep is, that it is never so complete as, under all circumstances, to prevent its excitement. On this alone it depends, we shall find, that it has no fatal tendency. The degree of sensibility which remains in sleep, is the distinguishing mark between it and the torpor of disease. That sleep alone is healthy from which we are easily roused. If our fatigue has been such as to render it more profound, it partakes of disease; that is, as will appear more clearly from what I shall have occasion to say of the different species of apoplexy, the vital system partakes of the debility, or some cause is operating which prevents the restoration of the sensitive system.

Distinct as the vital and sensitive systems are, we know that neither can long survive the other. In a paper which ap-

* Philosophical Transactions for 1829, and Experimental Inquiry.

peared in the *Philosophical Transactions* for 1829, I stated or referred to the facts which prove that in all modes of death, except the most sudden, arising from causes which so impress the nervous system as instantly to destroy all the functions, those of the sensitive system are the first which cease. The animal only dies when his means of enjoyment and intercourse with the world which surrounds him, no longer exist; this consequence is constant, and never long delayed. It is necessary, therefore, to a clear view of the state of the functions of the animal body in sleep, to determine the bonds of union between the sensitive and vital systems, at first view so distinct, which render their existence, except for a very limited time, inseparable.

That the sensitive cannot exist independently of the vital system, is evident, on the slightest consideration; but the dependence of the latter on the former is much less so. The facts stated in the paper just referred to, prove that in the more perfect animals, the function of respiration, being the only vital function which requires the co-operation of the sensitive system, is here the bond of union. It appears from those facts, that the muscles of respiration are, in the strictest sense, muscles of voluntary motion, the excitement of which consequently depends on the powers of that system. When the power of sensation wholly ceases, we cease to breathe.

So confused have been the ideas of physiologists on this part of the subject, that to account for the continued action of the muscles of respiration, and their intimate connexion with the vital system, they have supposed a third class of muscles partaking of the nature of both the others, those of voluntary and involuntary motion, to which it has been alleged the muscles of respiration belong. If this be the case, these muscles must change their nature every instant, because they are the same muscles which are employed in a thousand other acts universally acknowledged to be mere acts of volition; and, on the other hand, when powerful causes impede the breathing, all the muscles of the trunk are employed in this function. Besides, the facts which have been laid before the Society prove not only that there is no such class of muscles as that here supposed, but that the laws of excitability are the same in all muscles, the difference between the muscles of voluntary and involuntary motion depending wholly on the nature of their functions, and the circumstances in which they are placed. The nervous influence, although equally capable of influencing both, is supplied to them in different ways, and for different purposes, the usual functions of the muscles of volun-

tary wholly, of involuntary motion in no degree, depending on that system. The action of the muscles of respiration continues during sleep, because the exhaustion of the sensitive system is not complete, and the cause which influences this system in their excitement, continues in our sleeping as well as waking hours; and the same is true of all other muscles of voluntary motion, as far as the causes which induce us to excite them are applied. In the soundest sleep we move our limbs if their posture be rendered uneasy. Are we not obliged to guard against these causes in sleep, else the motions they would produce would quickly rouse us. Those of respiration are too gentle to produce this effect.

The only change which takes place in the action of the muscles of respiration during sleep is, that in proportion as the sensibility is impaired, they are excited less readily, and the act of respiration is thus rendered less frequent, a more powerful application of the cause being required; the consequence of which is, that when they are excited, the air is drawn in with greater force; hence, and from the relaxation which is apt to take place during sleep in the parts about the fauces, the cause of snoring*. Thus we generally observe that the snoring is the louder the slower the breathing, that is, the relaxation of the fauces being the same, the more profound the sleep. The loudest snoring I ever heard, so loud as to startle the attendants, was in the last ten minutes of the life of a person who died of a disease of the brain impairing the sensibility, and who only breathed three or four times during that space.

The other changes observed in the vital system in sleep, are evidently the consequence of the diminished frequency of respiration. This necessarily produces a proportional diminution in the frequency of the pulse; the properties of the blood being less frequently renovated in the lungs, it less readily excites the heart and vessels, and the diminished force of circulation is as necessarily attended with a diminished formation of the secreted fluids. This state of the vital organs, in its turn, influences the sensitive system, and thus the sleep is rendered more profound. While health continues, however, the vital powers are never sufficiently impaired to prevent the perfect restoration of those functions by which the animal is again

* Such facts are adduced in the paper last referred to as, I believe, will be admitted to prove that respiration is at all times an act of volition, excited by the sensation caused by the want of fresh air in the lungs; and the more the sensibility is impaired, the want must be allowed to become the greater, in order to excite the effort which relieves it.

fitted for intercourse with the external world.

The foregoing positions are well illustrated by the symptoms of apoplexy, in which a cause exists that prevents this restoration, and which consequently point out to us in a more striking manner the influence of the sensitive on the vital system. Here we find, that in proportion as the sensibility fails, the respiration, and with it the pulse, continue to become slower; and when it has failed altogether, so that no cause of irritation can excite any sensation, the respiration ceases, and the loss of circulation soon follows. In this way the patient dies in sanguineous apoplexy, where the cause of derangement is a gradually increasing pressure on the brain, in consequence of which its sensibility is at length extinguished. Here there is no original disease of the vital organs. Could the sensibility be sufficiently maintained to preserve a due frequency of respiration, and nourishment from time to time be introduced into the stomach, life would go on as in sleep, till the increasing affection of the brain, extending from the sensitive to the vital parts of that organ, so deranged the assimilating processes as to destroy life in this way.

The accumulation of phlegm in the lungs in apoplexy arises from these processes being deranged by the failure of nervous influence. I have repeatedly, in apoplexy, removed this accumulation of phlegm, the breathing becoming as free as in health, by causing voltaic electricity to pass through the lungs in the direction of their nerves. This, it is evident, can have no direct tendency to remove the disease, although by its means life may often be prolonged, and thus more time afforded for the application of the means of cure, this accumulation of phlegm greatly impeding the due change of the blood in the lungs, and thus conspiring with the diminished frequency of respiration to deprive it of its vital properties*.

A short comparison of the symptoms of apoplexy from compression, with that which is with great propriety termed nervous, will throw additional light on this part of the subject.

It is shown by experiments detailed in papers which appeared in the *Philosophical Transactions* for 1815, that although the power of the heart and vessels is independent of the brain and spinal marrow, causes operating on these organs are capable of influencing them, and that even to the total destruction of their power. When, therefore, the cause of apoplexy, instead of

being a gradually increasing pressure of the brain—which I have found by experiment, however powerful it may be, has no direct influence on the action of the heart*—is of such a nature as, while it impairs the sensibility, also directly impairs the power of the heart and blood-vessels, we have a disease of a very different nature from apoplexy from mere compression. In the latter, if we can remove the cause of pressure, and prevent its recurrence, we invariably cure the disease; there is no other cause of derangement. The vital functions are only impeded by the want of the due change of the blood in the lungs, in consequence of failure in the functions of respiration and assimilation. Death here is necessarily slow, because it always requires some time for the gradually increasing pressure either to destroy the sensibility, and consequently wholly stop respiration, or so derange the assimilating processes, as in this way to prove fatal; for from some peculiarity in the cause, the effect of which more readily than usual spreads to the vital parts of the brain, death, in apoplexy from compression, sometimes appears rather to arise from this derangement than the loss of sensibility, the phlegm gradually accumulating in the lungs till it wholly prevents the necessary change of the blood effected in them†.

But when the cause, which impairs the sensibility, also through the ganglionic system immediately enfeebles the heart and blood-vessels, the course of the disease is very different. We have here a cause at once impairing the powers of circulation; and when it is excessive, death is often instantaneous. Such is the cause of death from blows on the head, which, when not sufficient to produce instant death, produce what is called concussion of the brain, in which a state analogous to syncope is combined with impaired sensibility. The circulation is doubly assailed by the direct diminution of the power of its organs, and a failure in the stimulating power of the blood, in consequence of its less perfect decarbonization, and the former being the more powerful cause, obscures the effects on the vital organs of the latter. The pulse, instead of being slow but regular, and of unimpaired strength, is feeble, irregular, and fluttering, and a general paleness of the surface indicates a degree of failure of circulation, far beyond what is observed in cases of mere compression.

* Experimental Inquiry, third edition, Part II.

† This accumulation of phlegm in the lungs has been found experimentally to be the uniform consequence of lessening the supply of nervous influence in the lungs.—*Philosophical Transactions* for 1827 and 1828; and *Experimental Inquiry*, Part II.

* Experimental Inquiry, third edition, Part III. On the application of the experiments to explain the nature and improve the treatment of diseases, Chap. 1.

All sudden and excessive affections of the brain may produce the same effects as the blow on the head. Thus, people have instantly expired from rage or excessive joy, and thus in the mobs of Lord George Gordon, some from the sudden effect on the brain through the nerves of the stomach, expired on taking a draught of spirit of wine which they had mistaken for common gin.

But it is not necessary that the cause, as in these cases, should be either sudden or violent to produce this species of apoplexy. A long-continued recurrence of slighter causes, weakening the powers of the brain, often, along with them, gradually impairs those of the heart and blood-vessels, in the same way that an infusion of tobacco, applied to the brain in the experiments above referred to, impaired their powers. These are the most common causes of nervous apoplexy; and in proportion as their operation has been slow, the course of the disease is less rapid.

Thus we see it supervene in those who have been long exposed to the irritations which attend the more serious and confirmed cases of indigestion or long-continued causes of anxiety, particularly in gouty habits, in which there is often a great tendency to debility in the vital organs; and we readily perceive, from what has been said, why apoplexy from such causes is so generally fatal. The powers both of the nervous and circulating systems are undermined, and with them the secreting and other assimilating processes which depend on them. The powers which ought to respond to our remedies have failed. Our efforts therefore are for the most part equally unavailing in restoring either the sensibility or the powers of circulation, and both are necessary to recovery.

From a review of the whole of the facts which have been laid before the Society, it appears,—

That in the brain and spinal marrow alone reside the active parts of the nervous system.

That the law of excitement in the parts of these organs, which are associated with the nerves of sensation and voluntary motion, is uniform excitement followed by proportional exhaustion, which, when it takes place to such a degree as to suspend their usual functions, constitutes sleep; all degrees of exhaustion which do not extend beyond them and the parts associated with them, being consistent with health.

That the law of excitement in those parts of the brain and spinal marrow which are associated with the vital nerves is also uniform excitement, but which is only, when excessive, followed by any de-

gree of exhaustion, no degree of which is consistent with health.

That the vital, in no degree partaking of the exhaustion of the sensitive system in sleep, only appears to do so in consequence of the influence of the latter on the function of respiration, the only vital function in which these systems co-operate.

That the law of excitement of the muscular fibre, with which both the vital and sensitive parts of the brain and spinal marrow are associated, is interrupted excitement, which, like the excitement of the vital parts of these organs, is only, when excessive, followed by any degree of exhaustion. And

That the nature of the muscular fibre is every where the same, the apparent differences in the nature of the muscles of voluntary and involuntary motion depending on the differences of their functions, and of the circumstances in which they are placed.

I shall conclude this paper with a few observations on dreaming, immediately connected with the preceding parts of the subject.

Had we, independently of experience, been made acquainted with the nature of sleep, we might have foretold that dreaming—pretty much as we find it—would be its consequence.

We here find the sensitive parts of the brain, to which the powers of mind belong, and the parts associated with them, in a state of exhaustion, but not such exhaustion as prevents their being excited by slight causes, while other parts of the system are still in a state of activity. But it is only in the most perfect state of health, and such as we rarely enjoy, that the vital functions are performed without slight causes of irritation arising in some of their various and complicated processes, which tend to disturb the repose of the sensitive parts of the brain. Thus it is that indigestion and other internal causes of irritation produce dreaming. Such causes act partially, and therefore only partially excite those parts.

It seems greatly to influence the phenomena of dreaming, that in order to favour the occurrence of sleep, and thus as far as we can prevent unnecessary exhaustion, means are always employed at its accustomed times, to prevent, as much as possible, the excitement of the external organs of sense, and consequently those parts of the brain corresponding with them. This renders us the more sensible to causes of excitement existing within our own bodies, while, by the inactivity of those parts of the brain which correspond to the organs of sense, we are deprived of

the usual control over such parts of the mental functions as are thus excited; the effect of which is greatly increased by the rapidity of the operations of the memory and imagination, when not restrained by some of the various means employed for that purpose in our waking hours. These are often objects of the senses, as written language, diagrams, sounds, and sometimes even objects of touch; but the most common is the mere use of words, independently of any object presented to our senses.

Any one may easily perceive how difficult it is to pursue a train of reasoning without this means of detaining his ideas for the purpose of steadily considering them, and comparing them together. Now, in sleep, in consequence of the excitement of the brain being so partial, we are deprived of all these means; and our ideas pass with such rapidity as precludes all consideration and comparison. Our conceptions therefore are uncorrected by experience, and we are not at all surprised at the greatest incongruities. Why should we be surprised at our moving through the air, when we are not aware that we have not always done so? The mind of the dreamer differs from that of the infant, in having a fund of ideas laid up in it which may by various circumstances be partially recalled; but it resembles it in being in other respects void of the results of experience, and consequently, with the exception of this partial operation of experience, of the means of correcting the ideas excited in it. In general, there is neither time nor means for doubt or hesitation.

Such is the rapidity of our thoughts in dreaming, that it is not uncommon for a dream, excited by the noise that awakes us, and which therefore must take place in the act of awakening, to occupy, when put into words, more than fifty times the space in the relation. It is a good illustration of what is here said, that when we dream that we are conversing, and thus obliged to employ words, the usual incongruities of dreaming do not occur. The ideas are sufficiently detained to enable us to correct the suggestions of the imagination. No man ever dreamt that he was telling another that he had been flying through the air.

Thus the peculiarities of dreaming arise from the partial operation of the causes of disturbance, and some of the sensitive parts of the brain being capable of excitement without disturbing others; and thus it is that the more near we are to awaking, the more rational our dreams become, all parts of the brain beginning to partake of the excitement; which has given rise to the adage, that morning dreams are true.

DISLOCATION OF THE HIP, WITH FRACTURE OF THE THIGH.

To the Editor of the Medical Gazette.

SIR,

A CASE of dislocation of the hip, complicated with fracture of the thigh, successfully treated, having occurred in my practice, I forward the particulars, which, should you deem them of sufficient interest, you would much oblige me by inserting in your valuable journal.—I am, sir,

Your obedient servant,

JOHN C. BLOXAM.

Newport, Isle of Wight,
August 10, 1832.

G. M., æt. 14, a healthy country labourer, was admitted into the Hospital for the Poor, under my care, on Dec. 2d, 1832, the wheel of a loaded waggon having passed over him a few hours before.

On examination, it appeared that the right thigh-bone was fractured a little above its middle, and that the head of the bone was dislocated, and rested on the os pubis. When the patient lay on his back, the knee was bent and inclined away from the other, the knee and foot being turned on the axis of the limb, so as to point very much outward. The limb was much shortened, three or four inches at least; there was considerable tumefaction and tenderness about the groin, where the hard and fixed head of the bone could be felt without much difficulty. The right arm was also fractured, just below the insertion of the deltoid muscle, and there was a slight graze on the left thigh, but no other material injury.

He could give but a very imperfect account of the manner in which the accident happened, having no recollection of his position when the wheel passed over him.

The patient being in such a state, I did not think it proper to attempt the reduction of the dislocation at the time, and therefore bound up the limb in short splints, and ordered an evaporating lotion to be applied to the groin. At the expiration of seven or eight days the swelling had in a great measure subsided, rendering the head of the bone much more distinct; the tenderness had much abated; all inflammatory symptoms had disappeared under low diet

and antimonial and aperient medicines, taken during the week; I therefore determined to attempt to reduce the dislocation in the following manner:—

The patient was laid on his back on the bed, and kept in that position by means of a sheet passed across the pelvis, and fastened to the bedstead; another sheet was also passed over the left groin, and secured in a similar manner. The dislocated and fractured limb was then enclosed in splints, one of which extended up the back of the thigh as far as the tuberosity of the ischium. Pulleys, which were secured to a staple in the ceiling, placed at the distance of a foot to the right of a point vertical to the patient's navel, were then attached to a bandage fastened round the splints, as high up as possible.

The foot was raised with the knee extended, so as to bring the limb nearly to a right angle with the line of the tackle, when, by drawing gradually on the cord, in the course of about ten or fifteen minutes the head of the bone was rendered moveable, and was brought considerably more forward. I then began to press on the head of the bone, so as to push it downwards, whilst the pulleys held it partially disengaged from the pelvis. In a few minutes the head of the bone passed over the ridge of the os pubis; and I then directed the foot to be raised a little higher, which, by putting the glutei muscles more upon the stretch, was calculated to render them more efficient in drawing the bone into its proper place. By this manœuvre the head of the bone was drawn backwards; and on the foot being more elevated, and the cord slackened, it continued to recede from my fingers till the trochanter major made its appearance in the natural situation, and the reduction was found to be perfectly complete.

Lest the head of the bone should slip backwards on the dorsum illi, I directed an assistant to apply firm pressure during the latter part of the process, above and behind the acetabulum.

The apparatus was then removed, the thigh bound up in short splints, and the patient laid upon a double-inclined plane. No symptoms of inflammation appeared afterwards about the joint. Passive motion was employed at the end of a week, and occasionally repeated during the whole reparatory process.

At the end of eight weeks he was taken out of bed; he had then partially

recovered the power of moving the limb, which has gradually increased, so that he has for many weeks been able to move it without difficulty in any direction; and to walk with only a trifling degree of lameness. He is at present able to run about and work in the fields as well as before the accident, and he is not sensible that the limb is in any respect inferior to the other; but I find by measurement that it is shorter than its fellow by nearly half an inch.

It will have been perceived that I adopted a different method of reducing this dislocation from that recommended by Sir Astley Cooper for dislocation of the thigh forwards. His method, if it had been practised in the present case, would have been quite unavailing, as the extension would merely have separated the broken ends of the bone from one another, instead of moving its upper extremity.

PRESENCE OF UREA IN THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

WE have observed in the columns of the last No. of your journal, some observations from a correspondent respecting our recent communications. He wishes, in the first place, to know the number of specimens of morbid serum examined by us, in consequence of the doubt which he considers we have expressed as to urea ever existing in the blood; secondly, he asserts that no one ever supposed urea to be always present in the blood obtained from patients labouring under anasæra with coagulable urine; thirdly and lastly, he states that no one (but ourselves) ever imagined that a urinous odour was indicative of the presence of that principle.

Now, sir, in answer to his first question, we briefly reply—six, three of which were obtained from the wards of Guy's Hospital, the other three from private sources.

In proof of our statement, that urea has been supposed the cause of the peculiar symptoms manifested in the disease under consideration, we shall merely refer your correspondent to pages 380 and 383 of the No. of your Gazette for June last.

With respect to the statement, that no one but ourselves ever considered the urinous odour as sufficiently determinate in proof of the presence of urea, we beg to observe, that although the odour of urine cannot be taken as a test for demonstrating the presence of urea (as we have recently proved), still as no one before ourselves had made known the peculiar re-action of nitric acid on the alcoholic extract obtained from the coagulated healthy serum, and as the odour thus evolved has always, up to a late period, been considered as peculiar to the urine alone, and not existing in any other secretion, we were, in our first experiments on diabetic urine, led to conclude, that the urinous odour must have been developed from some substance proper to urine, and that that substance was urea.

The number of experiments performed by us we do not consider as decidedly disproving the presence of urea in every case, but they clearly prove that it cannot exist in the majority of cases, and therefore cannot be the cause of the train of symptoms manifested in any one case.

Your correspondent considers that the crystalline plates formed by nitric acid are the only test to be relied on; but he should remember, that urea is not solitary in this particular respect: thus that principle called stearine, which may be obtained by means of alcohol from the coagulated serum of healthy blood, especially when that fluid contains more than its ordinary share of fatty matter, will, by the action of nitric acid, produce crystalline plates, which fuse and become dissipated by heat, and even undergo solution in about twenty-five parts of water. There are, indeed, several properties which will distinguish these two bodies from each other; and these have been noticed by us when we stated at length the characteristic behaviour of urea towards different re-agents. We shall conclude by observing, that we have no right to consider urea to be present in the blood, unless we can obtain a sufficiency of the crystalline plates produced by the action of nitric acid, to subject them to other tests besides those above-mentioned, which are common to nitrate of urea and nitro-stearic acid.—We are, sir,

Your obedient servants,

R. H. BRETT.

GOLDING BIRD.

Guy's Hospital, August 19, 1833.

CASE OF DIFFICULT LABOUR, FOLLOWED BY HYSTERITIS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case worthy the notice of your readers, its insertion in your journal will oblige

Your humble servant,

DANIEL F. TYERMAN.

Guy's, August 6, 1833.

Dorothy Mahony, æt. 28, of short and stout figure; confined in her first labour. I was called to her on Tuesday at noon, June 25th, and found the pains forcible and frequent. They commenced the previous morning, at five o'clock, and continued more or less up to this period. A midwife had been in attendance, and prematurely ruptured the membranes. On inquiry, I found that my patient had not passed water for forty-eight hours. A very large ovoid tumor, filling the right iliac fossa, and ascending some way into the abdomen to the right side of the uterus, was recognized, from its fluctuation, to be the distended bladder. On attempting to introduce the catheter, the child's head offered a firm resistance to the progress of the instrument. The pressure of the fingers had no effect in raising the head, which was found firmly moulded on the brim, with the scalp much tumid. Accordingly it was found necessary, by introduction of the hand, to obtain the full bearing of the wrist on the child's head, which now, with very considerable pressure, was raised, and a groove being formed by the fingers and tumid scalp, the catheter passed perpendicularly into the bladder; the instrument being withdrawn during the continuance of a pain. A very large quantity of urine passed. The tumor of the bladder receding from the touch, and its tenderness, which was exquisite, subsiding, much relief was obtained. The pains continued, and an examination detected a funis presentation. The cord was returned beyond the head, but presented again. No pulsation was felt. Accordingly, turning the child was thought of. This proceeding, however, from the narrow and angular form of the pelvis and projecting promontory of the sacrum, together with the firm contraction of the uterus about its contents, was found quite impracticable. The

fingers laid behind the symphysis pubis detected the ossa pubis meeting at an angle, and a slight lateral curve was evident in the lower part of the spine. No pulsation returned to the cord, and the case was left to nature. The head, at 4 P.M., was firmly impacted, and the pains continuing, the child was born dead, without the aid of instruments, at half-past 7 P.M. Uterus contracted and placenta separated. Pulse good. No difficulty occurred in the birth of the child with regard to the outlet of the pelvis, which was large.

Ordered Tr. Opii, $\mathfrak{m}\mathfrak{x}\mathfrak{l}$. statim.

June 26th, morning.—Has slept slightly. Uneasiness and diffused pain of the abdomen; thirst; tongue dryish and coated in the centre; face flushed; pulse 110, somewhat hard. Has not passed urine, or voided lochial discharge. A large quantity of urine was drawn off by the catheter, which afforded relief. Uterus rather large and high; its fundus exquisitely tender to the touch; its sides not so much so. No distinct pain in other parts of the abdomen is caused by pressure.

Ordered Mist. Salina cum Magn. Sulph. et Tr. Hyosciami, 3tiis horis.

Evening.—More thirst. Frequent, severe, and cutting pains in uterine region. Uterus more exquisitely tender—the slightest touch cannot be borne. Pulse 110, hard. No lochia.

Venesection, $\mathfrak{L}\mathfrak{x}\mathfrak{x}\mathfrak{i}\mathfrak{v}$. Calomel and Colocynth purge, followed by Castor-oil, with Tr. Hyoseyami.

The bladder inactive. The catheter covered with a black offensive stain.

27th, morning.—Expresses herself much relieved. Appears much more tranquil. Has slept the greater portion of the night. Uterus bears some pressure. Scarcely any lochia. Pulse 96, and tranquil. Bowels open.

Rep. Mist. Salin.

28th.—Sleeps well, and frequently. Pulse 92, tranquil. Uterus bears pressure better. Small coagula have passed. Urine passes involuntarily.

29th.—Improving. The state of the bladder improved. Small quantities of urine are retained, but more passes involuntarily. Bowels purged.

Mist. Cret. cum Conf. Arom. et Hyd. c. Creta.

299.—XII.

31st.—Bladder has more power. Uterus bears handling, still is large and high in the pelvis. No lochia.

July 1st.—Uterus is again more tender; frequent, cutting, and severe pains in uterine region. Thirst; pulse 110; bowels not open. A mild calomel and colocynth purgative was given, followed by castor-oil.

Evening.—Bowels relieved. Much restlessness. Cutting pains in uterine region. Uterus more tender to the touch. Pulse 104, with some hardness.

Venesection, $\mathfrak{L}\mathfrak{x}$. Mist. Salin. 4tis horis.

2d.—Is better. Cutting pains have left her. She has not slept. Uterus bears scarcely any pressure.

Hirud. xij. Hypogast. Hot fomentations.

3d.—Much improved. Does not sleep. Uterus bears pressure better.

Ext. Hyosc. gr. iv. Cal. gr. j. horâ somni. Mist. Salin. rep.

5th.—In all respects better. The bladder has now perfectly recovered its power. She obtains scarcely any sleep. Slight lochial discharge.

6th.—She slept for four hours last night; appears fast recovering. Pain in micturition has been relieved by Copaiba with Pulv. Tragac. Comp. Uterus still large and high.

She speedily advanced to recovery from this time, and in a fortnight was able to call on me, complaining only of slight lameness and œdema of one foot.

THE GUNNER WITH THE SILVER MASK;

BEING AN EXTRAORDINARY CASE

OF EXTENSIVE DESTRUCTION OF THE LOWER JAW BY A SHELL;

With an Account of the Recovery of the Patient, and a Description of an Ingenious Contrivance for Remedying the Loss of Parts.

THE following details have been communicated to us by SIR WILLIAM WYMPER, to whom they were furnished by a distinguished military friend.

In presenting the following descrip-

tion, and in calling to it the attention of our readers, it is our duty to express our most cordial thanks to the French and Belgian medical officers in charge of the Antwerp hospitals, and above all to Dr. Forjet, Surgeon-major to the Army of the North. This eminent practitioner kindly furnished us with copies of notes extracted from his official report to Baron Larrey, and we have done little more than arrange and alter them in an English garb.

The advantages enjoyed by the French medical department, at the siege of Antwerp, were never before surpassed during any similar operation. The instant a man was wounded in the batteries or trenches, he was conveyed to the field hospital at Hoboken, where the first operations and dressings were instantly performed. The slighter cases were then removed to the general hospitals at Louvain and Malines; those of a graver nature to that of Boom or Antwerp, where every possible convenience, comfort, and even luxury, were abundantly supplied, and where the sufferers received every physical and moral succour that art or humanity could devise; and there were many of the wounded who shewed a degree of gaiety and indifference, though suffering the most acute pains, that must have been the fruit of extraordinary stoicism, or of rare exaltation of mind. The subject of the following details was amongst the latter number.

Alphonse Louis, aged 22 years, a native of St. Laurent, in the Pas de Calais, private in the 5th company, 2d regiment of artillery, of a sanguine temperament, was wounded in the trenches on the 6th December, 1832, by the splinter of a shell. When this misfortune occurred, Louis stood fronting the left wheel of his gun. He held a lever or handspike across his body, in the proper position of a gunner waiting to serve his piece; that is, with the right hand raised and the left depressed, or the very reverse of the position of an infantry officer when holding his sword diagonally, at open order, preparatory to a salute. At this moment a 12 inch shell burst a few feet above the battery, and a fragment of about seven pounds weight struck Louis.

The projectile first attacked the external part of the left jaw, carrying away almost the totality of the maxillary process, of which there only remained the edge of the extreme left pos-

terior portion, the coronoid process, and condyle. On the right side, the extremity of this bone was preserved as far forward as the first large molar tooth, inclusive. Besides this, the alveolar processes and teeth of the upper left jaw were partly fractured, the body of the hyoides laid bare, the left parotid duct lacerated, and the tongue furrowed on the same side with a deep wound.

The loss of substance, or solution of continuity, occasioned by this wound, was immense; it extended on the left side from the zygomatic process to the antero-superior articulation of the thyroid cartilage, tearing away almost all the fleshy parts of the cheek, and a large portion of the upper lip; on the right side it ran from the same cartilage to a level with the upper maxillary sockets and the buccinator, to within half an inch of the lobe of the ear. The centre of the wound was occupied by lacerations of the roof and coating of the palate, by the cesophageal opening of the throat, by some remnants of the upper maxillary glands, and the hyo-gloss and genio-gloss muscles; and lastly, by the tongue, swollen to four times the size of its ordinary volume. This organ having been entirely denuded on its lower superficies, as far as its base, and having lost its natural support, hung down in front of the larynx. In short, to render the description still more clear, nothing whatever remained of the lower jaws save the four fractured double teeth, and injured fragment on the right side, and thus the tongue drooped down to the length of several inches, exposing the cavity of the throat, a horrible and ghastly sight.

But the sufferings of the victim did not terminate here; the splinter, after committing this fearful havoc in the face, encountered on its descent the upraised right arm, and striking it about one-third of the distance from the elbow to the wrist, caused a compound fracture of the severest kind.

Louis was immediately raised, and carried from the battery to Hoboken, where the surgeon-major on duty forthwith proceeded to sew up several portions of the integuments of the upper maxillary region, as well as those of the neck; that is, both above and below the solution of continuity, in order to diminish the aperture. But the nature of the laceration was such, as to offer little hope of saving the patient; indeed, such

was the nature of the mutilation, that death appeared not only inevitable, but ardently to be desired. The amputation of the fore-arm was then performed by the ordinary process, at the distance of about two inches below the articulation of the elbow-joint. The usual dressings were applied in both instances. Symptoms of general re-action were not long in developing themselves,—at first not with a degree of severity proportionate to the gravity of the wounds. The most rigorous diet was enforced. The wounds of the face, fearfully swollen, were dressed every day without any remarkable accident; and on the 11th of Dec., or sixth day, the sewings and first dressing of the fore-arm were removed; and on the 12th the patient was carefully transported to the reserve field hospital at Boom. On the following days the same treatment and regimen were continued, and Dr. Forjet was not without hopes of saving the man's life.

The suppuration now commenced in both wounds; it was of a satisfactory nature, as regarded the stump of the arm, but of a less favourable character in the face, of which several mortified portions gradually sloughed away. Between the 14th and 24th days the gashes in the face assumed a livid and gangrenous character; the suppuration was more unwholesome, and the dressings more painful than ever. The stump having become the seat of considerable inflammation, the bandages were removed, and emollient cataplasms applied; notwithstanding this, however, the extremities of the bone pierced through the fleshy parts near the lips of the wound, and their death was the inevitable result.

On the 2d of January, or twenty-eighth day, the patient was transported from Boom to the military hospital at Antwerp, and placed under the immediate care of Drs. Forjet and Sentin.

From the 2d to 20th January the dressings could only be effected by the aid of the chloruret of sodium; these were renewed daily. But notwithstanding the most energetic treatment, and the most indefatigable attention, the aspect of the wounds was extremely unpromising, and nothing could arrest the gangrene. However, between the 15th and 20th the surfaces assumed a less unfavourable appearance, and the local and general symptoms were attended with a slight amelioration. This amelioration progressively advanced, in con-

sequence of the unremitting care with which the patient was attended. The nourishment at first consisted of some slight doses of thin broth, afterwards veal soup and lemonade tinged with wine, and then with vegetable and animal jellies. In proportion as the muscles of the tongue regained some slight power, the deglutition of these substances became less laborious and painful. They were administered by means of a narrow curved spoon, moulded for the purpose, the extremity of which was placed on the base of the tongue, and the food, always administered in a liquid state, poured down the œsophagus.

From the 25th January to 9th February the progress of general and local amendment became more sensible daily, the edges of the wound subsided to a level with the circumjacent surface, and the work of cicatrization manifested itself. The tongue was now reduced to within double its ordinary volume, and the exfoliation of bony substances continued insensibly. The cicatrization of the stump was only impeded by the complication before-mentioned. The portion of dead bone came away on the 9th; other fragments had been previously removed, and the whole appeared in a promising state.

A singular circumstance attended this part of the case, and merits peculiar attention. Although the gustatory surfaces were diminished by nearly three-fourths, and the tongue had lost its action—although alimentary substances only came in contact with a small part of the posterior portion of the tongue, and the mucous membrane of the bronchial passage (which generally are not admitted to possess the faculty of distinguishing or appreciating the savour of any given nutriment, but merely that of facilitating deglutition), it appeared that the sensation of taste, though at first much impaired, was now exercised with perfect discernment.

On the 10th February an exact plaster cast was taken of the face, thus horribly disfigured; it being sufficiently cicatrized to permit this operation without causing great suffering to the patient. A cast-iron mask was then made; and by the aid of this the artist was enabled, at his leisure, to construct a substitute for the lost parts, that might not only render essential service to the individual, but even deceive the eye as to the ravages of the wound. From the

10th to 25th the process of cicatrization made rapid progress. The palate, uvula, the whole of the injured superior surface and adjacent membranes, had returned nearly to their natural state, and the phenomena of deglutition gradually increased in the regularity of their functions; however, the extent of the vault of the palate was still much diminished, and its surface covered with a thick white crust, demanding constant ablution. The left parotid was paralyzed, and the salivary process only went on by the right side. On the other hand, the stump was in a highly satisfactory state, and almost entirely cicatrized. The general condition of the patient was, in every other respect, that of the most promising convalescence.

The integrity of the vocal organs having remained unimpaired, it is unnecessary to observe that the voice continued unchanged; this, however, was not the case with the powers of articulation, which could not of course act from the want of the front of the mouth. It is not, however, uninteresting to remark, that the phenomena of speech were not totally annihilated; that the simple and compound vowels were uttered naturally, and that the greater part of the consonants were pretty distinctly enunciated; the labials and hissing sounds were the most indistinct. Nevertheless, the mere habit of attending to the patient sufficed to render his language intelligible, and an improvement in his mode of pronunciation was gradually perceptible; so much so, indeed, that there was every ground for predicting that the modifications in his power of articulation would be susceptible of great improvement under the influence of time and education. This prediction has already been partially verified; for on our last visit to Alphonse Louis, we were able to comprehend every word he uttered; and the wounded men occupying adjacent beds in the hospital, said that they understood him as well as any other of their comrades. He appeared to speak without any great effort, or pain. The sounds were not loud, but sufficiently so to be heard at a reasonable distance; and gave one the idea of a person speaking with a wooden gag placed transversely between the open jaw, and pressed against the back of the mouth.

On the 25th Dr. Forjet made some at-

tempts to separate the morbid fragments of the right jaw, and succeeded in detaching the whole portion of the bone that incommoded the patient, and prevented the precise application of the artificial substitute. The rest of the operation was left to nature; and four days subsequently the splinter separated itself from the live parts. It consisted in front and below of the whole thickness of the maxillary body; and above, of the bone that separates the 5th and 6th dental socket. On the outside it was composed of the extreme portion of the body and branch of this bone, including its obliquity, terminating backwards in the coronoid process. The patient still preserved on this side the three large molars, of which the first, imbedded in a half socket, forms the antero-posterior base of the maxillary bone, and might resist for a length of time the ordinary causes of destruction.

It was at this time that the last finish was given to the artificial *silver* substitute, the execution of which had been intrusted to a skilful artist of Antwerp, M. Verschuylen, from the designs of Dr. Forjet. The ability shewn by the artist in the construction of this ingenious piece of mechanism, is deserving of much commendation; and we venture to recommend such of our readers who may have an opportunity of visiting the Invalids at Paris, to inquire there for the "*Gunner with the Silver Mask*;" they will then be enabled to inspect the contrivance, and to see and converse with its proprietor. To practical men the visit will be of deep interest. A short description of the mask itself is necessary, though we cannot pretend to offer a graphic portrait.

The external part is composed of a lower half-mask, without nose or cheeks. The anterior edges are in immediate contact with the lower part of the nasal cartilage and adjacent muscles, and the angles of the upper jaw. The two sides, or half-cheeks, repose on the parotid borders of the maxillary and the sternomastoidæa, so as to conceal and enclose the whole extent of the deformity. In the front of its centre, that is, the portion occupied by the lips and chin, there is an oblong square plate, or trap, opening with a lateral hinge and spring; this imitates the surface of the chin, two lips, and middle section of the mouth. This trap being opened by the patient's left hand, shews a second, or internal

chin, and complete buccal cavity, with a regular set of metal teeth. By the aid of this aperture, of which the mechanism is extremely simple, a communication is opened between the air and the pharynx, so that he can repose and breathe freely without taking off his mask. This is not strictly necessary for the process of respiration, as there is an opening between the artificial lips; it is merely done to give greater freedom to the action of the lungs, and to diminish the heat.

All the points of contact with the face are skilfully ornamented with mustachios and whiskers, which entirely cover the edges. The inferior parts are covered by the cravat; and the posterior part, which reaches behind the ear, hidden by allowing the hair to grow and fall down over it. At the distance of two or three yards it is impossible to distinguish the artificial nature of the substitute; the subject having the appearance of a man of good constitution between 45 and 50 years of age. The mask is painted in oils, of a tint analogous to his complexion, so that the illusion is so strong that, unless forewarned, he might be steadfastly examined at a short distance without betraying his misfortune.

The internal part is divided into two compartments. The upper, or sublingual section, is furnished with a platform which supports the tongue, retains it in its proper position, and regularly circumscribes its action by a complete alveolar process, set with gold teeth. This jaw, being adapted with a hinge and spring, can be lowered at will by the man's left hand, so as to admit food. The lower section forms the cavity of the inward chin, and is disposed so as to serve as a reservoir for the saliva and mucous secretions, which are incessantly flowing from the remaining parotid and glandular integuments of the mucous membrane; these fluids are got rid of through a small orifice, by merely leaning the head to one side. The different portions of the mask are of silver, strongly gilt, and so constructed that they can be taken to pieces in order to undergo cleansing, and can be re-united with the utmost facility. The whole contrivance, an admirable proof of mechanical skill, is maintained in its proper place by means of Indian rubber bandages, which hook on the occiput and vertex, and are strengthened by

means of a flexible metallic strap, intended to prevent all possibility of derangement. The weight is about three pounds, and the cost of the whole was about 12*l.* sterling.

The use of the mask is by no means painful or inconvenient, considering the nature of the wound. It is, above all, of great assistance in arresting in their passage, and retaining in the cavity of the artificial chin, the salivatory and mucous secretions; it facilitates the action of the tongue; it has restored a face dreadfully mutilated to a human form; it has singularly softened the rigour of the sufferer's fate, conducing to his comfort, and rendered his existence not only desirable, but comparatively happy. On our last visit to Alphonse Louis, the day previous to his departure for Lille, he appeared in high spirits; he walked about with agility; used the stump of the fore-arm with address; took off and readjusted his mask with his left hand; spoke not only intelligibly but easily; he was high-coloured, and fatter, as he stated, than he had ever been prior to his misfortune. He played at cards, and seemed to be as proud of shewing the mechanism of his artificial jaw, as he was of the crosses of the Legion of Honour and Leopold, that glittered on his bosom.

It would be in our power to detail several other most interesting operations performed by Dr. Forjet during the siege, but we have already occupied too much of the reader's time with the description of the "*Gunner with the Silver Mask*," whose history, though less romantic than that of the celebrated "*Iron Mask*," is infinitely more interesting to science and humanity. Of the one, all that can be said is, that he was the mysterious victim of that most unparalleled despotism that paved the way to the first French revolution; in the other, we have a proof of the glorious triumph of art, and of the immense progress of medical skill. Wounds of a similar nature are not unfrequent; there is an instance, we believe, of something analogous in the case of Colonel Cunningham; but as far as we have been able to ascertain, no recovery from such complicated lacerations is on record in France, nor had the substitution of an entire artificial jaw ever been projected, or successfully executed, until the present instance.

EFFECT OF DUST, AND OTHER SUPPOSED IRRITANTS, ON THE LUNGS.

BY M. PARENT DUCHATELET.

A SPECULATOR in Paris wished to establish a magazine for beating carpets: the neighbours complained of it as a nuisance, the matter was referred, by the Board of Health, to M. Parent Duchatelet, and his answer contains some interesting particulars. Three objections were taken to this carpet-beating establishment: 1st, its insalubrity; 2dly, its being disagreeable on account of the noise; 3dly, the depreciation effected in the adjoining property. Of course we have only to do with the two first. The chief point insisted on was the bad effects of the particles of wool floating in the atmosphere; and to decide this, the reporter visited the apartments in all the hospitals in Paris where the mattresses are made up; and the result was uniformly, that if the persons employed were previously well they retained their health even in the atmosphere so charged with dust that one could scarcely see in it; but that if the person were already phthisical, or disposed to phthisis, he could not bear it. The same inquiries were instituted at the various military establishments in the French capital, and with the same uniform results. They also visited the establishment of M. Ternaux, at Ronen, where the hair of the Cachemire and Chamois is beaten. It is impossible to form an idea of the thick and suffocating dust in this place, and yet, according to the statements of the workmen and of M. Ternaux, it did not affect the health, though it was extremely disagreeable. The reporter saw several operatives, and even some Arabs who had not quitted the establishment for several years.

There are in Paris a number of places in which ten or twenty women and upwards are employed in cutting the fur of hares and rabbits: their clothes and even their hair become covered with it: they breathe immense quantities of it, because they can only work in a closed apartment; nevertheless, these women enjoy good health, and generally continue the occupation during many years. In confirmation of the above it may be added, that hundreds of hatters have

been examined, and found to enjoy the most perfect health, with entire freedom from any pulmonary affection.

These illustrations may suffice as to the effect of dust considered as an animal substance, and as conveying miasmata or other principles of disease. Let us next view them as mere mechanical agents. If clay or silex, reduced to powder, could by their introduction into the chest produce spitting of blood and phthisis, what would become of our coachmen and postilions, our travellers, and a host of persons whose houses are by the road-side?

Plasterers (into whose state we have inquired at all the establishments in Paris) suffer no inconvenience: the workers in charcoal are insensible to the dust of the charcoal, though it be hard enough to polish metals.

If individuals, whose respiration is more or less disturbed, and who are painfully affected by slight barometrical changes, or who are threatened with consumption, are exposed to an atmosphere clouded with dust, there can be no doubt of its being injurious, but it does not appear that disease is originated by such cause, although it may be aggravated when already present. In a public point of view, the reporter regards the most serious objection to establishments for beating carpets in the midst of towns, to consist in the most monotonous, deafening, and almost unceasing noise, which they occasion*.

REPORT ON THE EXPOSING FOR SALE THE FLESH OF ANIMALS,

Which have died of various Diseases.

BY M. HUZARD.

THE disadvantage arising from the sale of animals which have been diseased, has been pointed out to the government, and means have been taken to prevent this abuse, as dangerous to the health of persons in straitened circumstances, who generally use the cheapest food. The first point to be ascertained is, what diseases, in animals intended for the butcher, can give to the meat its hurtful qualities. One only presented this character—viz. malignant pustule,

* Annales d'Hygiène Publique: Juillet 1833.

(*charbon*). There are now well-authenticated examples of accidents resulting from the use of animals which have died of, or been slaughtered while labouring under other complaints. There are even numerous instances of persons having eaten the flesh of animals who have died of carbuncle, without experiencing any injury, while those who have cut up the carcases have been affected with malignant pustule. It would appear that the act of cooking destroys the contagious poison of this disease, which, with hydrophobia, is almost the sole disease communicable from the lower animals to man. (Has the reporter forgot the vaccine?) The contagious typhus fever of cattle, which prevailed among them in 1814-15 and 16, did not prevent thousands of the diseased animals from being eaten, without any accident leading to the belief that the food was injured. From time immemorial, the flesh of cattle labouring under pulmonary consumption in various stages, has been consumed in Paris without any inconvenience resulting. It appears, therefore, to be well ascertained, that animal food so changed in cooking may be regarded as free from danger. In a public point of view, then, there are but two kinds of flesh the use of which requires to be prevented—namely, that which is spoiled, and that of animals having had malignant pustule. In Paris, great attention is directed to these points, and no cattle in a suspicious condition are allowed to be slaughtered without a certificate from a veterinary surgeon as to the safety of doing so, as regards the consumers*.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Treatise on the Diseases of the Eye. By W. LAWRENCE, F.R.S. &c. &c.

THERE are few departments of the healing art which have been more assiduously cultivated of late years than that of ophthalmic surgery. Numerous valuable essays and papers on particular points have been published, and we have also had more than one systematic treatise. To this last class belongs the

work before us, and with the exception of Mr. Mackenzie's *Complete Practical Treatise on the Diseases of the Eye*, it is the most elaborate which has hitherto appeared in an English garb. The opportunities enjoyed by Mr. Lawrence, in having been for many years one of the surgeons to the London Ophthalmic Infirmary, together with his general professional knowledge, and his acquaintance with German literature, have afforded him advantages of no ordinary kind in the construction of his work, in which we find the combined results of his own practice and observation, with the science and experience of the most eminent surgeons on the continent. The anatomy and physiology of the eye are succinctly detailed, but with great clearness, and with sufficient minuteness to serve the purpose of an introduction to the pathology and treatment. These last subjects are fully and satisfactorily discussed, and the whole subject handled in a manner consistent with the previous reputation of the author. We extract the section on the curious subject of parasitic animals, because it is suited to our limited space, and at the same time illustrates the character of the work:—

“*ENTOZOA (internal or parasitic animals) in the eyes of man and of other vertebralia.*”

“It has been long well known that a species of filaria (thread-worm) is occasionally found in the anterior chamber of the horse's eye, moving rapidly about in the aqueous humour. The circumstance, though rare in these climates, is by no means uncommon in India, where it is only seen during the cold months, not having been observed before the beginning of October, or later than the end of February, or the commencement of March. The heavier the rains have been during the periodical rainy season, and particularly towards its close, the more numerous have cases of worm in the eye been during the subsequent cold season. They occur chiefly in low districts, being hardly known in the upper provinces, where the soil and climate are drier. Mr. Gibb, surgeon to the East India Company's stud at Poonah, used to see about twenty cases annually. Thirty cases occurred in one season, at Poonah, among the young stock, while in another depot, situated higher (Ghaze-

* Annales d'Hygiène Publique ; Juillet 1833.

poor), not a single case occurred during the same time. Two worms have sometimes, but rarely, been seen in the same eye at one time; and a second worm has made its appearance in an eye from which one had been extracted some months before. Similar worms are met with in the stomach and intestines of the horse; also, according to some reports, in the cellular substance of the loins. The animal, which has received the name of *filaria papillosa*, is about an inch long, equal in size to a sewing-thread, white or darker coloured. It causes inflammation of the eye, with measiness, watering, and turbidity of the anterior chamber. Opacity of the cornea comes on, and blindness ensues. These results may be prevented by extracting the animal. A small incision is made in the cornea with a lancet, and the worm comes out with the aqueous humour.

"This worm has been seen in the horse's eye in Europe*.

"In the work just quoted, Dr. Nordmann, of Odessa, describes the circumstances which led him to discover the existence of entozoa in the eyes of several vertebralia; and he gives a minute account of them, illustrated by beautiful figures, representing their form and internal structure. His researches, which were carried on during eighteen months, from March 1830 to September 1831, embraced numerous eyes of horned cattle, sheep, pigs, frogs, lizards, and fishes, with some from the human subject, and birds. He found entozoa of the genus *filaria* in the human eye, and in that of the gadus aeglefinus (haddock), of the genus *ascaris* in the frog, of the genus *oxyuris* in the perch, of the genus *cysticercus* in the pig, and *trematoda* in great abundance in other fishes. The genera examined for this purpose were mureno, gadus, perea, gasterosteus, cobitis, silurus, cyprinus, salmo, esox, pleuronectes. In the fish he first found entozoa in the vitreous humour, but he subsequently met with them in the crystalline, between the lens and its capsule, between the laminae of the cornea, in the iris and retina, in the choroid gland, between the sclerotic and retina, and in the aqueous humour. In the crystalline lens of some fish they are so nume-

rous as to render it more or less opaque, and thus to impair or injure sight.

"A species of *filaria* (*filaria medinensis*?) has been seen under the conjunctiva oculi in the West Indies. Schön has quoted some facts of this kind. A case was related to him by Dr. Gaertner, who had resided long in the West Indies. A blackish thread-like streak, which moved, was seen in the conjunctiva of a negro girl. In a little time it had disappeared, and a slender bluish line was observed in the upper eye-lid. It appeared like a small cutaneous vein, and moved in various directions. Dr. Gaertner considered it to be the guinea-worm; he made an incision, and extracted the animal.

"Dr. Nordmann examined two lenticular cataracts, taken from an elderly man, half an hour after they had been extracted by Professor Von Graefe. In one of these, which was still partially surrounded by the capsule, he observed in the Morgagnian fluid two very small and delicate rings, which he clearly recognized under the microscope as convoluted *filariæ*. One of the two had been injured in the middle, probably by the cataract needle, so that the intestines had come out of the body, and were visible as slender threads. The other was uninjured, of uniform thickness, three-quarters of a line long, and extremely narrow. It was spirally convoluted, and completely dead. A simple intestinal canal, a mouth without visible papille, an uterus, and a prominent anal aperture, could be distinguished. In the other lens, which, as is usual, was completely free from the capsule, nothing similar could be discovered. Dr. Nordmann calls this entozoon *filaria oculi humani*. He adds, that he had since examined several cataracts, and human eyes under various circumstances, without discovering any entozoa.

"In a second part of the same work, the author recites two additional instances of entozoa found in the opaque lens. He says, 'In the month of May 1832, I was present at two operations of extraction performed on old women, by Professor Juengken. I found a living *filaria*, five lines and a half long, in the act of casting its skin (in der häutung begriffene), in one lens of the first patient, a case of green lenticular cataract. No extraneous living body was disco-

* Nordmann, Mikrographische Beiträge zur Naturgeschichte der Wirbellosen Thiere; Erstes Heft, p. 11-13.

vered in the other lens. The second case was more interesting, as it presented the first example of microscopical entozoa possessing suckers (*trematoda*, Rudolphi), being found in the human eye; eight individuals of the genus *monostoma* were found in the substance of the lens. These minute beings were situated in the upper strata of the crystalline; they were one-tenth of a line long, and moved sluggishly when placed in warm water. The examination took place immediately after the operation. In both cases the opacity was not yet complete, and the lenticular substance was soft.

“ Dr. Gescheidt and Professor Von Ammon found, in the crystalline lens, four entozoa of the genus *distoma*, in a case of congenital cataract.

“ *Cysticercus cellulosæ* in the anterior chamber of the human eye.—This hydatid, consisting of a small globular vesicle, with a slender neck, of which the end is a little enlarged, so as to form a kind of head, which is found all over the body of the domestic pig under certain circumstances, occurs also in the eye of the animal, where it has been seen both in the anterior and posterior chamber. It has been twice observed in the anterior chamber of the human eye, floating in the aqueous humor. Dr. W. Soemmerring communicated the first instance to the assembly of German naturalists at Heidelberg, in the year 1829; it was published in the *Isis*, 1830, p. 717, from which Dr. Nordmann has taken the following account:—

“ A living *cysticercus*, of the size of a vetch, was formed in the anterior chamber of the left eye of a girl eighteen years old, and otherwise healthy. It was said to have shown itself after an acute inflammation of the organ. I saw, and delineated it, two months afterwards, when no trace of inflammation remained, excepting a slight blush of red round the cornea, on excitement of the organ. It caused no pain, or merely a transient uneasiness when it moved considerably; and interfered with sight only when it came before the pupil. Usually it lay at the bottom of the anterior chamber, like an imperfectly dissolved lens, where it appeared as a partially transparent sphere, from which there was, at one point, a milk-white opaque prominence. In this situation the thick wrinkled portion of the neck

occasionally projected, sometimes spontaneously, sometimes in consequence of gently rubbing the upper eye-lid. Then slowly came out the thinner thread-like half, ending in a head with four suckers and a double circle of hooks. (The latter circumstances, however, were not distinguished till the animal, after extraction, had been examined with the microscope.) The body of the animal changed its figure, more or less quickly, from the ordinary globular to an oval or pyriform shape. It generally lay half a line from the margin of the cornea, on account of the narrow interval between the two parts at their circumference. The neck hung downwards like a leaden plummet. It was not attached, but moved freely, and changed its position according to the movements of the head, always passing downwards. In the course of seven months it had become twice as large as when first observed, and had attained the magnitude of a pea, when it was extracted alive by Dr. Schott, through a small incision of the cornea. It was put in lukewarm water, and continued to move more than half an hour; it then became gradually opaque and white, and we could plainly distinguish with the microscope the four prominent suckers with their orifices, and the double circle of hooks in the middle of them. As it corresponded in all respects, not only with the delineations of Göze and Bremser, but with other similar specimens from the human body, which I compared with it, I could have no hesitation in considering it as a *cysticercus cellulosæ*, which, so far as I know, has never been observed in the human eye, although, according to Van der Hoeven, it is found in that of the pig.

“ The case of another patient, in whose eye there is a living *cysticercus*, has been recently published by Mr. Logan, of New Lanark, in a pamphlet which I have not seen. A description of the appearances, illustrated by two woodcuts, has been sent to the *London Medical Gazette**, by Mr. Mackenzie, of Glasgow. The disease exists in a lively and otherwise healthy girl, seven years of age. From the month of August 1832, to the following January, there had been repeated attacks of inflammation in the left eye, which had

* Vol. xii. p. 110—112.

rendered the cornea nebulous, and still continued so severe as to threaten loss of sight: the inflammatory symptoms, however, subsided, leaving a slight opacity of the cornea. 'After a week the child was again brought to Mr. Logan, who, on examining the eye, discovered, to his great surprise, a semi-transparent body, of about two lines in diameter, floating unattached in the anterior chamber. This body appeared almost perfectly spherical, except that there proceeded from its lower edge a slender process, of a white colour, with a slightly bulbous extremity, not unlike the proboscis of the common house-fly. This process Mr. L. observed to be of greater specific gravity than the spherical or cystic portion, so that it always turned into the most depending position. He also remarked that it was projected or elongated from time to time, and again retracted, so as to be completely hid within the cystic portion, while this, in its turn, also assumed various changes of form, explicable only on the supposition of the whole constituting a living hydatid.' Mr. Mackenzie found the cornea slightly nebulous; he adds, 'When the patient kept her head at rest, as she sat before me in a moderate light, the animal covered the two lower thirds of the pupil. Watching it carefully, its cystic portion was seen to be more or less spherical, and then to assume a flattened form, while its proboscis I saw at one moment thrust suddenly down to the bottom of the anterior chamber, and at the next drawn up so completely as scarcely to be visible. Mr. Meikle turned the child's head gently back, and instantly the hydatid revolved through the aqueous humour, so that the proboscis fell to the upper edge of the cornea, now become the more depending part. On the child again leaning forward, it settled like a little balloon in its former position, preventing the patient from seeing objects directly before her, or below the level of the eye, but permitting the vision of such as were placed above.' As the child is healthy, and the eye free from inflammation, it has not been thought advisable to institute any treatment in reference to this parasitical inhabitant of the anterior chamber."

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL CHARITIES AND SELF-SUPPORTING DISPENSARIES.

WHILE shallow scribblers of the daily press, and (to their shame be it spoken) some of those of the medical press also, go on to indulge their spleen and their ignorance in ungenerous insinuations against the motives of the members of our profession, it is gratifying that everyday's experience serves but to bring forth fresh proof of the real integrity of those motives, and of the truly-disinterested zeal with which, generally speaking, the proceedings of medical men are conducted. People may talk of occasional examples of medical men stickling for fees, and endeavouring to secure that remuneration to which they feel themselves entitled; but we believe the fact cannot be denied, that in no other profession are there so many instances of "very prompt effusion of beneficence and willingness to exert (what ought to be) a lucrative art where there is no hope of lucre." The steady remuneration of the clerical order, and the safe anticipatory method adopted by our legal friends, preclude the necessity of their gathering up the crumbs after the feast is over, or seeking for their dues after services are rendered: while the medical body have usually to contend with the ingratitude of human nature, and are forced to incur the charge of selfishness after they have bestowed all their pains on the mitigation or removal of suffering. Something of this, no doubt, is owing to the pride of the founders of our profession, who, in uniting the healing art to a more certain and lucrative calling, disdained to receive, for their works of humanity,

other than honorary fees. But it is not a little painful to consider how this custom has been taken advantage of in almost all subsequent times, and to find it occasionally hinted to medical persons who have attempted to recover by law what, by the fair dealing and courtesy of society, they should have obtained without trouble—to hear it, we say, gravely stated to them by judicial wisdom (in the words of Lord Kenyon), “that it has been understood, in this country, that the fees of a physician are honorary, and not demandable of right; and it is much more for the credit and rank of that honourable body, and perhaps for their benefit also, that they should be so considered.” This, to be sure, is a very flattering unction for the pride of professional merit,—a bait for the forbearance of medical claimants—but one entailing a serious tax on those whom it serves to silence: a way of getting rid of a demand most convenient for those who are burthened with no generosity. The surgical part of the profession, however, being understood to be entitled to fees, and forced on many occasions, for very subsistence sake, to shew the validity of their title—on them does the charge not rarely fall of being hard and mercenary in their dealings. But let all things be fairly taken into account, and it will, we think, be in general found that such proceedings on the part of surgeons are purely defensive, and warranted fully, in most cases, by the meanness of the people with whom they have to deal. Doubtless there is meanness to be met with in the conduct of many connected with the profession, and examples are sometimes brought before the public eye, of men actuated by sordid principles in the exercise of a liberal art, or in withholding (which is worse) their services where they see no chance of remuneration: but in a numerous profession, such examples must be allowed to be rare, and are chiefly made conspicuous in consequence of their rarity. The occasion of the call

is critical; a life, perchance, is at stake; and the fact of refusing to interfere where there is no prospect of an equivalent (so obvious and natural in other circumstances) is here looked upon as a monstrous inhumanity. The truth, in short, is, that the demands which are frequently made on medical men are very often most unreasonable, and founded upon nothing else than the easy generosity which some of our predecessors were in the habit of displaying, but which we plain moderns cannot well afford. Whence it is most evidently incumbent on all parties to understand fully how they stand related to each other; and among the many benefits which promise to arise from the spread of Self-supporting Dispensaries throughout the country, this we value as one of the chief—that while the right of medical men to remuneration becomes more generally understood, the sacrifices not reluctantly made by the profession in the exercise of their laborious duties, become at the same time more intelligible, in the ascertainment of those exceedingly humble terms on which the bodily wants of the poorer classes of society may be administered to. In this we surely possess one of those practical proofs of the innate benevolence of our profession to which we have already alluded, and a complete answer to the sneers of detractors: in this also we will add, do we possess in some measure the elements of a perfect reform in the internal economy of the profession, which will ultimately set it upon a stable and satisfactory foundation.

The business of getting up dispensaries, we are aware, is often denounced in no very measured terms: among the babble with which it is frequently assailed, the charge of jobbery is frequent; and a cotemporary, notorious for the foulness as well as the marvellous impunity of his aspersions on the profession, has recently reiterated that charge. Now putting out of the ques-

tion the fact, that every business performed by man for man, whether for pecuniary profit or otherwise, may in a certain sense be called a job; not forgetting at the same time, that there are few callings which do important jobs of this sort more disinterestedly than does our profession; whatever, in fine, be the jobbing of medical men in other matters, in this of the adoption of the Self-supporting Dispensary system, it must be generally admitted, that they are actuated by none but the most pure and honourable motives.

We have been led into these remarks by the perusal of Dr. Calvert's communication on the subject of Dispensary Associations, addressed to the late Commissioners on the Poor Laws. The results of the Self-supporting Dispensary system, as stated in that able document, are highly gratifying. Commencing, as those establishments usually do in every quarter, under circumstances of a very discouraging nature, experience soon confirms the fact of their great utility, and never fails to win the cordial support of the medical men; for it is proper to add, that so far from being by any means a job got up by practitioners, those associations, in many instances, have had to encounter a serious opposition from the latter. But wherever the system has been adopted, though opposed at first by many practitioners, as appearing to take from them the last chance of procuring any thing like a suitable remuneration for their labours from the poorer classes of the people, a better acquaintance with the true tendency of these institutions has generally served to conciliate all parties, and to secure their hearty concurrence. "As to the opposition founded (says Dr. Calvert) on the supposed probable admission of persons who can pay the usual remuneration, it may be remarked, that fewer of this kind will be admitted than are now into clubs, and much fewer than now go to charitable dispensaries; for a rule is laid

down on the principle of excluding those who live by capital, and although the Committee will have to make exceptions to this, still it is their interest to act fairly up to the spirit of it, and to take the advice of the surgeons in doing so, as well as to consider the surgeons' convenience, by insuring the regular attendance of the patients at the times appointed." And again, in corroboration of what we have just now observed, Dr. Calvert says, "I may add, that the surgeons connected with them (the Dispensary Associations), profess themselves, with few exceptions, to be perfectly satisfied, even in the first year. Their own experience, not theory, has shewn the advantage which surgeons derive from these institutions; and the medical opposition is subsiding just in proportion as the plan is understood; and in many places where the plan has been talked of lately, the surgeons have come forward with offers of cordial assistance, just as intelligent men will naturally do."

What the feelings of others are with respect to these establishments, it is worth while noticing from the same source:—

"Every committee speaks favourably of the results of their experience, and at Southam I find the following opinion from the visitor of the poor:—"As visitor of the poor of the parish of Southam, I have had full opportunity of becoming acquainted during the past year with the effects of the Dispensary, and I think it right to state, that, in my opinion, it has diminished the number of applicants for parish relief, and consequently improved the feelings of the labouring part of the population. Of upwards of 200 persons now subscribing, it appears that most probably *one-half would, but for that institution, have been at this time on their respective parishes.*" And at Lymington, out of the 300 who subscribed in the first month, 100 had before been attended by the parish surgeon; whilst the Coventry Report proves that it was the Dispensary alone which in the late depression of trade there saved many from the parish when in sickness."

In short, the more this excellent system is contemplated, and the better it is understood, the more grace, we are convinced, will it find in the eyes of all. So admirably, indeed, has it worked wherever it has been put into action with ordinary prudence and sagacity, that no reasonable fears can now be entertained of its failure any where. One danger, however, seems to hover round it (and of that danger it were well that all parties concerned should be apprized in time)—there is a temptation to cause it to be worked over-zealously. Attempts have been made, it seems, in certain places, to make these dispensaries schools of temperance and morality. Here lies a quicksand. The management of physical evils is surely quite enough for those who have the welfare of these establishments at heart: in this have we the great point on which all are agreed, and unanimity on any one point is well worth securing. But once the genius of proselytism and speculative reform is admitted to interfere in the concerns of these dispensaries, adieu to their good fortune; at least, so it seems to us: however desirable, however alluring, the end proposed may be, the likelihood of the means in question giving rise to feuds among parties now at peace with one another, is but too manifest to escape any, except those blinded with the zeal of fanaticism.

As to the objections which are sometimes made to the system of Self-supporting Dispensaries by persons not professional—for they as well as the medical men must at first have their objections—what Dr. Calvert says is very reasonable.

“These objections,” says he, “refer either to time or place, the goodness of the principle being admitted by all, and its general practicability having been already proved by benefit societies and sick clubs, before these dispensaries were established. In the country it has been said, that the

uniform low rate of wages makes the payments impossible, but that the plan will answer where there are at least temporary high wages, as in towns; in these, however, we find the argument reversed, and we are referred back to the country. In summer, we are told, there is a great difficulty, because the poor are well and will not pay; in winter, we are told, there is a greater, because they cannot. The fact is, however, that there are some difficulties in every place, and men's indolent fears are like their sight, to which things appear greater as they come nearer:—‘The indolent man saith there is a lion in the way.’ But it must not be forgotten that every argument which shews the greatness of the difficulty, is really (by shewing the extent of the distress which an apothecary's bill must produce) proving the greatness of the evil, and therefore the necessity for its removal.”

The principle, as it is mentioned in this extract, has been long since proved practicable from its operation in benefit societies and sick clubs. But Dr. Calvert does not leave the fact unproved that it is fully as practicable in the working of the Dispensary Associations, as in that of the societies just named. He goes into the question in considerable detail, and even proves that the balance is strongly in favour of the latter. The fact is, that in well-conducted dispensaries on the self-supporting principle, the medical attendants are shewn to derive even a higher rate of emolument than from the ordinary club system. But this is far from any thing like what at first sight it might seem to be—a postponing the interests of the poor for the better providing for the benefit of the practitioner. The advantages are reciprocal. Let us hear Dr. Calvert on this point also.

“I must remind the Committee, that they must carefully attend to the interest of the surgeons; I do not say this because it is just that a set of men should be fairly remunerated, who already are called upon for more gratuitous services than any other, who have had an expensive education, who gain a livelihood by laborious duties, exposed to many

contingencies, and who must live in a rank of society which will insure that liberality of sentiment and general moral respectability of character so essential to the welfare of the families upon whom they attend; or because, if the philanthropist sees that greater distress and moral evil attend these medical charges than any other, and feels they must at all events be altered, he may fairly be called upon to repay in some degree the professional man for any loss he can prove he sustains in consequence; it is not on these accounts that the Committee must attend to their interests, but because if they are injured the poor are the first to feel it, and these Dispensary Associations cannot go on without their cordial co-operation."

In former articles we have noticed the admirable features which these dispensaries present in inculcating a spirit of independence and well-regulated providence among the habits of the poor. In the paper so often referred to, amongst numerous examples of this we find the following:—

"Regarding the collection of the subscription, I would strongly recommend that the members be obliged to bring their money to the Dispensary. At first it was usual to send round a collector, but besides that this was difficult and expensive, the poor, as is frequently the case, thought he was asking a favour, and like all other people, they are apt to fancy the value of any thing is in some degree proportionate to the trouble and expense it costs them: where the system has been changed, and the names of those in arrear struck out, there has been at first some diminution of the numbers, but they soon found out they must be regular, and as in benefit clubs, provided accordingly, and the same may be done in clothing societies. At Coventry, 'the secretary attends six hours every day, and has full employ for that time; he or the dispenser receives the subscriptions at any hour, giving a receipt in the simplest manner on a card, and never takes money without the receipt card; a list of the defaulters is made out every Saturday, and no medicine allowed them; he takes money in advance; but not when past due; great strictness to rule is indispensable. At Burton, also, where, 'out of 6000 inha-

bitants, there was in the first year 1000 free members, the money is paid regularly and cheerfully, and the poor seem grateful for the favour: we make the father or mother the responsible member, which saves us a number of tickets, and gives us much less trouble in receiving; some pay a month in advance, but the generality weekly. We are very strict in fines, and adhere to our rules as much as possible.' Where the members are few, of course the times of payment will be restricted; and some arrangement must be made to suit those living in the country. Weekly payments are, in towns at least, better than quarterly, inasmuch as they prevent many a penny being spent; and it requires much less resolution to pay many single pence than one larger sum. Thus, Mr. Spilsbury, a surgeon of eminence at Walsall, and to whom the Dispensary is greatly indebted, says, 'I am quite sure that much of the success depends on these small payments.'"

The interest excited by these dispensaries, we are gratified in knowing, is greatly on the increase. To those who are desirous of obtaining a thorough acquaintance with the system, we have great pleasure in recommending the paper to which, in the preceding remarks, we have been so much indebted—the communication of Dr. Calvert to the Poor Law Commission. They will find in it a vast fund of information relative to the different plans, and modifications of plans, which have been hitherto tried in various parts of the country, as well as a multiplicity of detail on a most important part of the consideration—the expenses which must necessarily be incurred, more or less, wherever a self-supporting dispensary is established.

PROGRESS OF CHOLERA—THE NEW PREVENTION ACT.

Our information on the subject of cholera leads to the conclusion, that in most districts of the metropolis which have been visited by it, the disease is progressively declining. About Clerkenwell, and in some of the low situations along

the course of the river, it continues to a considerable extent, — but even in these parts has appeared on the decline during the last two days. Its chief ravages throughout have been among the aged and previously infirm, or the dissipated; and in many, the development of the malady, in its malignant form, has been attributable to the neglect of the early symptoms. It cannot, therefore, be too strongly impressed on the public mind, that at the present moment the slightest attack of sickness or bowel complaint ought to be instantly attended to, as these are for the most part easily obviated by proper remedies, while, if suffered to continue, they may pass in a few hours into a state from which the patients cannot be restored by any means hitherto discovered.

The Cholera Prevention Bill has passed both houses of parliament, and is therefore again effective. As yet, nothing has been done besides employing medical men to collect information, and make their reports in the proper quarter. This was accomplished at first through the assistance of private practitioners, but some medical officers of the army have now been appointed to the duty in question. We trust that the passing of the act will prove to be only a measure of precaution, and that it will not be requisite to put it in full operation.

CLINICAL OBSERVATIONS

ON THE

TREATMENT OF GOITRE BY SETONS.

By BARON DUPUYTREN.

From the "*Leçons Orales*," published periodically, under the Baron's inspection.

INDIVIDUALS of lymphatic constitution are exposed to goitre, a deformity which affects women oftener than men, and infants than adults. This gland, which in the healthy state weighs about two ounces, often reaches two pounds in weight when diseased. In the valleys of Savoy, where it is endemic, neither sex nor age escapes, and such is the influence of the climate, that adults going to settle in that region are liable to be attacked with the disease.

Different causes have been assigned as producing goitre. Foderé, in the curious details which he gives, admits, perhaps too exclusively, the influence of humidity joined to elevation of temperature.

In March 1833, two women came to the Hôtel Dieu: one, about 26 years of age,

had become affected with goitre, involving both lobes, many years before. A voluminous, elastic, roundish tumor, with a lobulated surface, was perceived. Its base was broad, and from an almost imperceptible size, it had rapidly increased. The voice was hoarse, owing to its pressure, and the return of the blood by the veins was impeded: the patient had head-ache and giddiness.

The other patient, who had arrived at adult age, had become affected with the disease at 12 or 15, which now exhibited itself as large goitre, occupying both sides of the gland. A seton was passed through both tumors, and after the suppuration had continued some months, she was entirely cured: at present, the only thing to be perceived is the cicatrix left by the seton, the goitre having almost entirely disappeared. A kernel, about the size of a small nut, hard and quite insensible, was to be felt, but it had been stationary for many years.

The first patient was treated in a similar manner, a seton being introduced at each side of the neck, and passed through both lobes of the thyroid. The gland became a little swollen, and there was pain in the right shoulder and headache, for which it was thought right to bleed her. Seventeen days after the adoption of these means, the gland had diminished by two-thirds, the pain had quite subsided, and every thing announced that the cure would soon be accomplished.

Let us consider the manner of practising this operation, and the action of other therapeutic agents. Among these last, iodine has of late years been employed in this disease with a kind of phrenzy: one would suppose that no goitre ought to resist this energetic means. In many cases, nevertheless, it does fail, and a little reflection might have led us to expect this. Goitre depends on different causes: sometimes it is merely an hypertrophy of the thyroid gland, at others it is a scirrhus degeneration, and occasionally it consists of cysts variously filled. Iodine cannot act in the same manner in cases so dissimilar, and accordingly in a considerable number of cases it has no more influence than many other things. It is proper to state, however, that iodine has effected some cures. Under these circumstances it is right that each practitioner should say what has done good in his hands: now the seton is that which has afforded me most advantage, and it is that which I prefer. It has of late been boasted as a novelty by M. Quadri, of Naples; but this is a mistake, no doubt involuntary, for, as we have seen, it was practised with success many years ago on one of the patients whose history has been mentioned.

A certain time after the introduction of the seton, the goitre may be seen to dimi-

nish, and the resolution which takes place gradually, is complete at the end of some months: it may even happen that the diminution continues after the removal of the threads and the healing of the wound. How does the seton act? This is not easily answered; but it matters little, the essential point being that it effects a cure. When the seton is introduced, there is always a great flow of venous blood; the stream, indeed, is alarming, but proves of short duration. It is like that which takes place from the nose after extirpation of a polypus, and which often produces syncope. By directing the patient to breathe freely on applying cold or a slight compression, the hæmorrhage is arrested. To produce its effect, the seton ought to remain some months, the period depending upon the progress made towards recovery. A necessary precaution in introducing the needle is, to avoid the thyroid arteries. I do not, however say, that the seton will always cure goitre. Scirrhus, for instance, is never favourably acted upon by this means; but hypertrophy, cysts, hydatids, in which iodine and other pretended specifics often fail, are the forms of the disease which yield most readily to the seton*.

A NEEDLE BURIED IN A MAN'S HEART.

THE following case was lately reported to the Academy of Medicine, by M. Renaudin. A man of the name of Louvet, a *limonadier*, from Calvados, came to Paris on the 13th June last, and took a lodging near the Barrière du Roule. He seemed very absent in manner; spoke in monosyllables; usually left his apartment early in the morning, and did not return till late at night. On the 29th there was found after him a note, in which he said he had always been an honest man, and would die so in the course of five or six days. On the 6th July he took to his bed, kept an obstinate silence, and was occasionally delirious. The following night he was found half strangled, with a cord round his neck: on being questioned, he said he did not know what he was doing, but that there were some villains who wanted to hang him, &c. He was taken to the Hôpital Beaujon next day; when he said, that about two months before he had had shivering, vomiting, pain in the side, and bloody expectoration. The cerebral symptoms now became aggravated; the pulse was 127; respiration 27; decubitus on the

left side. In an effort to rise, he fell back and expired.

On examination of the body, a large quantity of sero-purulent fluid was found in the pericardium. The apex of the heart was adherent; the heart itself more large and lengthened than natural. In the substance of the right ventricle was found embedded a needle, which extended into the cavity. The lungs were gathered up towards the top of the chest. No trace of a cicatrix by which the needle might have entered, could be discovered on the exterior of the body.—*Gazette des Hôpitaux*.

DEATH OF MR. ALCOCK.

It is with much regret that we have to announce the death of Mr. Alcock, of New Burlington-Street, which took place on the 21st instant. Mr. Alcock, whose health had long been declining, was well known as a most assiduous cultivator of his profession, and was the author of various works and papers evincing considerable talent and practical skill.

NOTICE.

The letter of Medicus we have been obliged, through want of room, to postpone till next week.

W. WILSON, Printer, 57, Skinner-Street, London.

* The remaining subjects in the present fasciculus of the "Leçons Orales," viz. *On Gangrene of the Limbs; on the Application of Arsenic to Cancerous Ulcerations; and on Dislocation of the Ulna*, have been already given in this journal, into which they were transferred from various sources; the same, it appears, from which the compilers of the "Leçons" have derived their reports.—TRANSL.

THE LONDON MEDICAL GAZETTE,

Medicine and the Collateral Sciences.

SATURDAY, AUGUST 31, 1833.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE URINARY
ORGANS.

—
NEPHRITIS.

THE first disease of which I shall speak among those of the urinary organs, will be according to the rule which I have hitherto observed, inflammation; and inflammation of the kidney, called *nephritis*.

Symptoms.—In this disease there is pain in the loins, but it is usually experienced on one side only. There is very frequently nausea and vomiting, on account of the great sympathy that exists between the kidney and the stomach. In inflammation of the heart and lungs you do not have vomiting, but in inflammation of the kidney you generally have more or less disturbance of the stomach, either nausea or absolute vomiting. From sympathy among different parts of the urinary system there is usually a frequent desire to make water; the pain is not confined to the loins, but runs along the ureter towards the bladder. The testicle of that side is generally painful and contracted, drawn up, and very frequently indeed it is swelled. There is also numbness in the inner part of the thigh, I presume from an affection of the anterior crural nerve. The pain is seldom felt at the back of the spine; it does not run down like sciatica, but is felt anteriorly along the course of the ureter, down the testis, and down the inner part of the thigh, where

the anterior crural nerve is situated. The testis, indeed, is sometimes not only swelled, but sore to the touch, and sometimes it experiences a sensation of numbness as well as the inner part of the thigh. The urine is generally scanty and red, following the course that is usually observed in any active inflammatory disease; and the kidney being the part affected, it is more scanty, and of a deeper red, in nephritis than in other inflammations. On the other hand the urine is sometimes deficient, and occasionally it is found to be very pale; but, as a general rule, it is scanty and red.

Diagnosis from rheumatism.—In a rheumatic affection of the loins the pain is usually felt on both sides, and it is felt to a great extent; it generally affects a large surface. It runs to the hip, and if it extend at all it proceeds down the outer part of the thigh, taking the course of the sciatic nerve. In this affection there is not a frequent desire to make water, there is no pain in the course of the ureter, no enlargement of the testicle, nor pain in the inside of the thigh. Motion in this disease very frequently produces pain, pain extending perhaps to the thigh, and especially about the joint, and about the trochanter. The large trochanter is not only painful, but perhaps hot and swollen; very often you have rheumatism in other parts, and very frequently there is profuse sweating. The absence of all urinary symptoms, if I may so call them, and the situation of the pain, in addition to the common symptoms of acute rheumatism, enable you in general to distinguish the disease perfectly. I was able the other day to make an accurate diagnosis where some little difficulty was thrown around the case. There is a man in St. Thomas's Hospital, who was there six or eight months ago, for a decided affection of one kidney. There was pain in one part of the back, which extended down the ureter, the testis was retracted, and there was an affection of the urine. The case was

treated as nephritis. But he now came in with what was decided rheumatism; there was pain on the outer side, lower down than the kidney; it did not extend in the course of the ureter, but particularly affected the joint, ran down the course of the sciatic nerve, and the joint was painful on motion, shewing the effect of rheumatism. He did not make water more frequently than he ought, but there was pain in one point anteriorly; that, however, arose from an evident circumstance—the pain ran along the glands, which were inflamed. He was treated by acupuncture, and making his mouth sore, and he speedily got rid of the disease.

Causes.—Nephritis may be produced by cold, like any other inflammation, but it is rarely an idiopathic disease; it more frequently is the result either of mechanical violence, or of some acrid matter which has been taken, such as turpentine or cantharides; or it is the result of stones existing in it, or of some disposition perhaps to gout.

Termination in suppuration.—If the disease go on to great violence, suppuration may occur, and then of course there is less pain; rigors may be experienced by the patient; pus may appear in his urine; the discharge may take place in that direction, or it may present itself at the back, giving the appearance of a lumbar abscess, perhaps; sometimes, however, it has been known to open into the intestines. Various terminations have occurred, all of which you may imagine beforehand. The pus has sometimes been collected into an abscess; sometimes it has appeared in separate portions, there have been so many minute specks with which the organ has been studded.

Treatment.—As to the treatment of the disease, of course you are aware that it consists of bleeding at the arm; cupping on the loins, either alone or after general bleeding; parging, especially by calomel; putting the patient into a warm bath, and low diet.

If the kidneys suppurate, it is necessary to treat it as any other suppuration. You must support the strength, tranquillize the patient by anodynes, and perhaps give uva ursi. Some recommend this drug, but whether it has any particular virtue I do not know. The common treatment of suppuration of any part of the body is that which is required.

HEMATURIA.

The kidneys are subject also to hæmorrhage; and when blood appears in the urine, the disease is called *hæmaturia*.

Causes.—Blood may appear in the urine from an affection of the kidneys, from an affection of the ureter, of the bladder, or

of the urethra, or of some other part opening into the kidney. The blood is occasionally diffused through the urine; you see the urine containing a sediment, which is evidently a mass of blood, and sometimes you see blood discharged without any urine.

Diagnosis.—If the urine be red in consequence of the presence of blood, I think you may always distinguish it by the eye; it is not of a deep orange colour, but a downright red. You may always distinguish it from the most red sediment produced by feverishness and inflammation; it is a true red, such as no one, I think, can mistake; but if you have any doubt, you may dip a rag into it, and you will find it stained red, without any tinge of yellow, or any orange tint, as is the case in the highest-coloured urine. But you have another point to ascertain. After you have distinguished whether it is blood or not (and frequently it is discharged so pure, or in such a quantity, that, independent of the colour, you ascertain at once what it is), you have also to find out where it comes from—whether it comes from the kidney, or some other part. If it come from the urethra, this is easily known, because there is evident disease of the urethra. It is common in violent gonorrhœa; it is common in stricture, and also when a bougie is passed. There can be no difficulty, I think, in ascertaining whether the hæmorrhage comes from the urethra: the point most difficult to ascertain is, whether it comes from the kidney or bladder. It is rare for hæmorrhage to take place from the ureter.

I presume the mode of distinguishing between hæmorrhage from the kidney or the bladder, would be by observing where the other symptoms reside, whether in the loins, or down in the pelvis. Sometimes I believe it is impossible to make an accurate diagnosis. I recollect having a case of fungus hæmatodes of the bladder, which was productive of no pain, no irritation whatever; the only symptom that the man had, was a discharge of blood from the urinary passages; I could make out no disease at all. He died under the repeated hæmorrhages; and at the autopsy a fungus was found shooting from the bladder. But if there be any symptoms besides the bleeding, emaciation, and debility, you will observe whether they are situated in the loins, or about the bladder. If they are in the loins, there will be pain there, most likely sickness, perhaps tenderness in the region of the kidney. If the symptoms are in the bladder, you have pain about the pelvis, a frequent desire to make water, far more so than in the other case; there will be far greater irritation. But it is to be remembered, that disease

of the bladder and urethra will cause pain in the kidney, and disease of the kidney will cause irritation about the bladder, as well as the symptoms I have mentioned about the testicle. The latter shew how distant the symptoms may be, when the kidney is itself affected. Hence it is to be remembered, that sometimes there may be great difficulty in making out an accurate diagnosis; but generally the presence of symptoms in the pelvis, rather than in the loins, or *vice versâ*, or the great intensity of the symptoms at one spot rather than at another, will be the means of removing all difficulty.

Treatment.—With regard to hæmaturia at large, it is a disease easily cured, or, on the other hand, it may be very dangerous; all depends upon the cause. It is sometimes inflammatory, attended with signs of nephritis, pain in the loins, feverishness, quickness of pulse, a dry tongue, and so on, even with retraction of the testicle, and will give way to the common treatment for nephritis. A bleeding or two, or purging, will generally get rid of it. When it is inflammatory it is acute, and generally arises from some evident cause, a cold, or a blow, or some acrid substances that have been taken, the most common of which, and indeed the only ones that I ever saw produce it, are turpentine and cantharides. When it has arisen from these, it would be well to take plenty of diluents and demulcent substances. Water with a quantity of gum in it, and mucilaginous matters in general, should be employed in addition to anti-inflammatory treatment.

Sometimes, however, this hæmorrhage is entirely passive; there are no signs of inflammation. It occurs sometimes with typhus fever, sometimes with small-pox, and sometimes with purpura hæmorrhagica. Because it is a symptom of purpura hæmorrhagica, that is no reason why it should not be inflammatory; but it will take place where that disease arises entirely from debility, as well as when it is inflammatory.

Under these circumstances the treatment for passive hæmorrhage must be adopted, and turpentine will be found very useful, not in large, but in small doses, from 20 to 25 drops every four or six hours. But, of course, the system requires support, and the common treatment of passive inflammation must be adopted at the same time that you employ this specific remedy.

When hæmorrhage takes place in chronic disease of the kidney—when you have seen chronic disease previously existing—when you suspect that there may be calculi in the kidney, or a cancerous affection of the organ, or any other structural disease, the same treatment must be adopted; you cannot in general lower the patient. If

there be symptoms of inflammation, you must act accordingly; but in general the administration of turpentine in small doses (carefully watching it lest it should irritate the kidney), together with the exhibition of opiates to relieve the pain and procure rest, and giving the patient good support, is all that is needful.

The treatment will give you no difficulty at all; you have only to treat it in the same way as hæmorrhage from other parts. You must consider what is the patient's strength, on the one hand, or his debility, on the other; you must consider whether there are symptoms of active inflammation, or how far the hæmorrhage appears to be passive only. If the disease be not inflammatory, you will find that oil of turpentine is of as great use here as in hæmorrhage from the alimentary canal; but it is necessary that you should carefully watch the patient, because that which is passive to-day may, through sudden excitement, be active to-morrow.

This hæmorrhage occurs sometimes in a curious way. Like other hæmorrhages, it has occurred where the menses have been suspended. I once saw an instance of its occurrence after hæmoptysis had been cured. Occasionally it will take place in men, and also in women; but more frequently in men who have been subject to a discharge of blood from the hæmorrhoidal vessels. When that discharge is stopped, they are in the predicament of a woman who is in a state of amenorrhœa. Generally speaking, these cases are not dangerous, but require antiphlogistic treatment. If the natural discharge of menstruation has ceased, and inflammatory hæmaturia has supervened, it may be right to attempt to bring it back again.

Chronic Nephritis.—The kidney is subject also to chronic inflammation, but you usually see the effects of chronic inflammation in the form of organic disease.

Hypertrophy.—Occasionally the kidney becomes enlarged: there is no particular alteration of structure, but the organ is evidently hypertrophied, and perhaps firmer than usual. I presume this is an inflammatory affection: over nourishment must be, one would suppose, more or less of an inflammatory nature, and that from the great activity of the circulation deposition has taken place.

Turgescence.—Sometimes the kidney will become very turgid, very red, merely as the result of a difficulty in the circulation. Sometimes after great dyspnoea—after obstruction of the heart—after obstruction of the lungs—the kidney has, on cutting it open, been found full of blood; so that you might at first mistake the appearance for that of active inflammation. But if there be active

inflammation, the kidney is generally found soft; whereas the effect of chronic inflammation of this organ is either induration or hypertrophy.

Paleness.—Frequently the kidney, instead of being red, is pale. After death has occurred through chronic disease, the body is generally found to be wasted; and not only is the brain, for example, and the muscles, pale, but the kidney likewise. The kidney, however, is sometimes pale through disease of its own, and then it is generally firmer and harder than it should be. You will recollect that when I spoke of induration as a common effect of inflammation, I spoke both of red and of pale induration; and each of these effects occurs in the kidney.

Mottled Kidney.—But the kidney is sometimes very red or pale only in spots, and then it has a mottled appearance; you have what is called a mottled kidney. Morbid paleness usually occurs in the cortical part, but sometimes the whole kidney is in this condition. Hypertrophy, attended with redness, when it is partial, occurs in the cortical portion, and that also will give rise to a mottled appearance. You may have a mottled appearance from one part becoming morbidly pale while the other remains natural; or it may arise from one part becoming morbidly red while the other retains its natural paleness.

Granulated Kidney.—Occasionally you will see the kidney granulated; small grains, more or less firm, are seen in different parts. Whether this is local hypertrophy or not, I do not know; but it is found most frequently in the cortical portion. These grains are of all numbers and all sizes.

Softening.—Occasionally the kidney becomes excessively soft, so that you may break it up with your fingers; and this, I presume, may occur very rapidly. I have no cases in point to support this opinion; but, judging from what occurs in the spleen and liver, I should think that the softening may be very rapid. I know that softening of the spleen or liver will take place in the course of a few days: a person shall be perfectly well, be suddenly taken ill and die, and you will find these parts so soft that you can run your finger through them in every direction, break them up in a moment; and therefore I can conceive that the kidney may become soft either in an acute or chronic way. When this organ is soft, there is the usual difference—that is to say, the softness is sometimes accompanied with redness and sometimes with paleness. Sometimes there is inflammatory softening, and sometimes this change appears to take place without any connexion whatever with inflammation.

Atrophy.—The kidney will sometimes waste; and if one waste, it is usual for the other to double its natural size, in order to perform the duty of both. Nothing is more common than to find one kidney enlarged in proportion as the other is diminished. This wasting of the kidney will sometimes proceed to such an extent that you will scarcely find any remains of the organ at all. I have met with cases where the kidney was discovered with the greatest difficulty; so that those who have first examined the body have said that there was but one kidney. What is termed a *horse-shoe kidney* is where there is only one; these, however, are rare cases, but the organ is sometimes wasted to a less size than a horse-bean.

Atrophy of the kidney sometimes takes place without any ascertainable cause: sometimes it is the result of inflammation, sometimes it is the result of abscess. A great discharge will cause atrophy of a part of the organ. We produce counter-irritation for the purpose of lessening morbid growths and morbid activity of the circulation; and if, without morbid growths and morbid activity, a discharge takes place by suppuration, the activity of the part is diminished, and wasting is a very common circumstance. An abscess, therefore, will occasion a part to waste, according to the general principles on which we employ setons and issues. But pressure will have the same effect: the pressure occasioned by a tumor in the neighbourhood of the kidney has been seen to produce atrophy of the organ.

It is stated by authors that atrophy of the kidney is sometimes partial, so that the medullary portion only is wasted, and the pelvis becomes a mere bag. Sometimes the cortical part is wasted, so that the cones within the kidney touch the fibrous membrane externally, and there is only a thin layer of cortical substance between. Thus you see there are various degrees of atrophy, and they have all been considered as a frequent result of inflammation.

Serous Cysts.—We have, however, other organic diseases of this organ: serous cysts are very common in the cortical substance, and by their pressure and growth they will cause an atrophy of it; and as they increase they cause more and more atrophy, till there is little more than a bag left. Cruveilhier has given a very good representation of these cysts. They are found more commonly in the kidney and liver than in any other parts of the body. Serous cysts are sometimes found under the external membrane of the kidney.

Fatty Kidney.—The kidney has sometimes been seen converted to fat. I presume a great deposition of fat has

taken place in the cellular membrane under the external coat, and the rest has wasted. Sometimes it has been converted into jelly. There is a peculiar substance sometimes formed in the kidney, called cholesterine; and the kidney sometimes contains a great quantity of it, causing atrophy of the kidney itself.

Other Diseases.—Occasionally encephaloid disease occurs in this part. You may have great disorganization of the kidney—you may have tubercles of various kinds, and even serofulous tubercles have been found here.

Symptoms of Organic Disease.—All these diseases may occur with very obscure symptoms, but sometimes they occasion dull pain in the region of one kidney, together with more or less disturbance of the stomach. Wasting away produces more or less disease of the kidney itself.

Diagnosis.—The diagnosis is generally difficult, unless the pain is very local, and unless the urine becomes morbid—very much affected: but even then, when you have satisfactorily made out that there must be organic disease, it of course must be very difficult, if not impossible, to say what that organic disease is. Scirrhus is said to occur in the kidney; but whether the affection is scirrhus, cancer, encephaloid disease, or a mixture of these, or a serofulous suppurative, it must be difficult to determine. If organic disease occur in a young person, and there is not much pain, you may suspect that it is encephaloid; if there be strong marks of serofula—if the ends of the fingers be enlarged—if there be mesenteric disease, or phthisis, you may suspect that the affection of the kidney is of a serofulous nature; or if the person be advanced in life, you may suspect scirrhus or cancer: but it must, as I have said, be very difficult to say what it is, and it can make no difference as to the treatment, which must be conducted on general principles.

DISEASE OF THE RENAL CAPSULES.

I may mention, as a point of pathological anatomy, that the renal capsules are rarely diseased, except from serofula; but I have frequently seen them in that condition. Sometimes they are indurated, and the induration may amount to cartilage, or even bone. As to the symptoms, nothing can be said on that subject.

Kidneys most frequently diseased in Men.—Dr. Baillie states, that, according to his observations, the kidneys are more frequently diseased in men than in women.

Having spoken of those diseases which are the result of inflammation of the kidney, and of structural diseases, I

will now proceed to consider functional diseases of this organ.

FUNCTIONAL DISEASES OF THE KIDNEY.

The kidney is subject to an increase or a diminution of its secretion: to secrete morbid urine—to secrete a substance which it ought not to form in that particular way, or, if it does produce it, should pass off with the urine; and besides these affections, the urinary organs are subject to the existence of worms.

ISCHURIA.

Divisions.—The first disease of which I will speak, will be a diminution of the secretion; and this is called *ischuria*. The suppression of urine, the absence of urine, or the diminution of it, which occurs in the kidney itself, is called *I. renalis*. If urine be formed in the kidney, but cannot escape, from some obstruction in the ureters, then it is called *I. ureterica*. If there be some obstruction in the bladder, it is then termed *I. vesicalis*. If there be obstruction in the urethra, it is denominated *I. urethralis*. There is no analogy in these different words. If the urine be suppressed—that is to say, if none be formed—we call it *suppression of urine*; if, however, it be formed, but cannot escape, we call it *retention of urine*: so that *I. renalis* and *I. vesicalis* are not at all analogous, and young beginners are often laughed at in the wards for saying suppression when they ought to say retention, and *vice versa*.

Symptoms.—The suppression of urine—a deficiency of the secretion—may be entirely inflammatory; and then you have symptoms of nephritis, and you must treat it as inflammation. But sometimes this complaint is unconnected with any symptoms of inflammation of the part, and it is certainly then a curious affection, for it is usually followed by apoplexy. No urine is made, or scarcely any, but at last absolutely none; you feel no fulness of the bladder—you pass an instrument into it, to ascertain whether it is a case of retention or not—you find that the organ is empty—and in general the patient very soon becomes drowsy; which drowsiness increases till he becomes decidedly apoplectic, and perhaps dies. Dr. Parr, in the London Medical Dictionary, mentions a case where no urine was made for six weeks; and Haller quotes an instance in which none was said to be formed for twenty-two weeks. These are very chronic cases, and one cannot answer for the truth of that which Haller alludes to. I presume he mentions it on the authority of another. The disease has sometimes been ushered in with rigors, and sometimes not. Some-

times it has occurred without any particular symptom till coma has made its appearance. Following the course of diseases of the kidney, it occurs more frequently in men than in women. It usually takes place in fat people who are upwards of fifty years of age.

Excretion from other organs.—When the urine has been so suppressed, occasionally it has evidently escaped from some other part of the body; and when the urine has not been suppressed, but has been formed, and not able to escape, in consequence of some obstruction, it has been absorbed, and has passed through some other organ. I know instances myself where it has been vomited; I saw a case where it passed from the skin, particularly the palms of the hands. Persons in these circumstances, who have made no urine, or whose urine, when secreted, could not escape, have occasionally vomited a fluid which smelt and tasted, and had all the qualities, of urine. Others have passed it in the form of sweat. There can be no doubt of the truth of these cases. I presume the fluid has been absorbed in the latter case, and re-secreted; and in the former case, it has been secreted originally, and has not been absorbed at all.

I. Renalis commonly followed by Apoplexy.—In ischuria renalis, it is very common for the individual to become apoplectic, and it is a very dangerous disease. I have had but one case of it, and that occurred after a person had taken a quantity of corrosive sublimate by mistake. Proper means had been used, and no harm was thought likely to occur; but after a certain time, the urine became suppressed, and I think the individual had hemiplegia, but I recollect perfectly that he became drowsy, and the drowsiness increased, till at length he became decidedly apoplectic, and died. One might imagine in such a case, that the same occurrence must have happened as when the urine has been vomited, or has been thrown off by perspiration, viz. that the urine was re-secreted into the ventricles of the brain. One would say, *à priori*, that that was likely to take place, or, if no urine was secreted, that an excessive quantity of fluid would be found within. Nothing, however, of the kind was discovered in this case; there was not only no urine in the head, but no excess of fluid either in or upon the brain. That was a result for which we were not prepared.

Treatment.—The proper mode of treating these cases is to give cantharides. I do not know whether oil of turpentine has been tried, but cantharides I know is a proper medicine. In the case I saw, a blister was applied, and the medicine was given internally, but the patient died within a few hours of its exhibition. However, a friend of mine had two cases which

occurred nearly together, in old people; and one of them was so bad, that Sir Astley Cooper, who was called in, had little hope of saving life, but he treated the case in a way which he said had been found to be successful, and the patient got perfectly well. In the second case my friend adopted the same plan, and it was attended with the same success. In the latter case it appears that the kidney had become torpid, but not through inflammation. Whether other diuretics would answer, I do not know; but it is said that cantharides should be given internally, and a large blister applied to the loins, in order that the medicine may have more effect, because the surface has much influence over the internal parts. When it is exhibited internally, it should be in the solid form, because the tincture is a most uncertain preparation. You should give a grain once or twice a day, or every eight hours, according as you choose. A grain is a pretty full dose; but in a case of this description there is no time to be lost, apoplexy may soon come on, and you should repeat the dose as long as it does no harm. I have given 10, 15, or 20 drops of the tincture, without any effect, and at last I have been obliged to give two or three drachms. The tincture, I presume, was not good; but it has been so common an occurrence with me to find the tincture either bad from its nature, or bad from its being so continually ill made, that I place no confidence in it in a case of life and death, where there is no time to be lost.

DIABETES.

Etymology.—The term diabetes is derived from the Greek word διαβαίνω, to stream through; the disease being characterized by the streaming away of a considerable quantity of water.

Hydrops ad Matulam an improper term.—This affection, on account of the excess of fluid, has sometimes been called *hydrops ad matulam*—chamber-pot dropsy; but as there is no accumulation of fluid, of course it would with great impropriety be called *dropsy*. In dropsy there is an accumulation of fluid—not merely a formation of it; it is formed faster than it comes away, and therefore it is termed dropsy: but as in this disease the water comes away, the word dropsy has been applied to it with the greatest absurdity.

Definition.—Diabetes is a word usually employed to signify chronic excess of urine. A person would not be said to have diabetes if he merely made a large quantity of urine for a day or two. The fluid may be either of a natural quality or it may contain sugar. As, however, there is no distinct single name for that disease in which sugar is formed in the urine, and as

it is sometimes formed without the urine being at all in excess, it would be well, perhaps, to restrict the term diabetes solely to saccharine urine, and to give such a name as *polyuria* to that form of the disease in which there is merely excessive quantity. But you find diabetes employed to signify a chronic excess of urine, whether there is sugar or not: the one being called *D. insipidus*, and the other *D. mellitus*, honey-like, sweet to the taste. It was to an excessive quantity of urine that the ancients applied this term; for it does not appear that they were at all aware that in diabetes the urine was ever sweet. I believe it was Dr. Willis, the English physician, who first pointed out that in this disease the urine was saccharine. The term is certainly employed by the ancients simply to a chronic excess of urine.

Frequently a temporary excess of urine in other diseases.—You are aware that there is frequently a temporary excess of urine in various diseases. In asthma, for example, a large quantity of pale urine is frequently made. So again, in hysterical and dyspeptic people this is often the case. You know likewise that fright will also cause a temporary excessive quantity of urine, so that persons who have been waiting anxiously to be called into a room, have been obliged to walk out twenty times in the course of an hour. Long-continued grief and anxiety have the same effect. I have known persons, from leaving off some of their clothes, make a considerable quantity of urine; and it has been remedied by wearing their usual quantity of clothes again.

D. Insipidus.—But independent of the circumstances I have now named, there is sometimes an excessive quantity of urine formed, not at all impregnated with sugar, and occurring without any evident cause. This form of the disease, which sometimes has, and might as well be called *polyurea*, is occasionally followed by that form in which the urine contains sugar; but sometimes it exists alone, and I believe that not unfrequently, after a length of time, it will cease. This incipient diabetes is more common in women than in men; the urine is very pale in general, and if it continues there is thirst and dryness of skin mechanically produced. An excessive secretion of water is going on in one part of the body, and there is therefore less water for the secretions of the mouth and skin. From the loss which the body sustains, there is also weakness and hunger.

Treatment.—This condition may frequently be recovered from by wearing warm clothing, employing the hot-bath, or going to a warm climate, and by the exhibition

of iron. Persons who have laboured under this form of the disease have, by medical men who have not properly examined the urine, been said to be cured of diabetes, as though they had had the saccharine form of the disease.

D. Mellitus.—In diabetes mellitus, or true diabetes, there is sugar in the fluid, and generally there is an excessive quantity of fluid also. The general symptoms that I just now mentioned are produced in this affection. From the loss which the body sustains there is great debility; from the body losing its nourishment, there is hunger; and from the want of fluid, there is thirst and dryness of skin. The hunger is sometimes excessive; so that the patient not only feels very hungry at the usual time of his meals, but he feels hungry during the greater part of the day. The food which the patient takes, does him (he says) no good, and he is presently anxious for more. Patients complain generally of a sinking at the pit of the stomach, and the uneasiness there occasionally amounts to aching. The thirst is sometimes so great that many quarts of fluid are drank in the course of the day, and the skin is sometimes so dry that the hair falls off. The feet and hands are frequently cold, there is lowness of spirits, and in almost every case peevishness and fretfulness. There is also one very remarkable symptom—the loss of sexual power and desire. I have never myself found this symptom absent, and sometimes it has been the very first symptom noticed by the patient. I never had a patient labouring under diabetes, in whom the feeling of sexual power and desire had not ceased entirely, or become very much impaired. This symptom is not noticed by all authors, and a patient of course will not mention it to you; but if you make it a point to inquire into it, you will, I believe, nearly always find it to be a fact. There is also frequently pain of the loins; but whether it arises from an affection of the kidney, or is merely a symptom of debility, I do not know. Although the whole body becomes emaciated, there is frequently oedema of the legs, and usually there is costiveness. From the deficiency of fluid in the alimentary canal, there is not only dryness of the skin, and thirst, but the tongue is sometimes white and clammy; frequently, however, it is smooth and red, and the saliva and mucus are excessively tenacious, so that the patient is very much annoyed. The gums sometimes become very red, and slightly ulcerated. The saliva is occasionally sweet, and so likewise is the breath. Dr. Latham says that the body smells like hay. I have not observed this; but the breath frequently smells sweet—has some-

thing of the odour mentioned by Dr. Latham. Very often there is redness and soreness of the end of the urethra: I have seen even phymosis;—this may, perhaps, arise from the irritating quality of the fluid. We usually find the pulse quick, perhaps full, and at last it becomes weak. There is a hectic appearance in the patient's face; you frequently find a flush upon his cheek, as well as quickness of the pulse, and at last you have decided hectic. In many cases there is great sweating: I have frequently seen it. Phthisis is a very common termination of this complaint; indeed the majority of patients whom I have attended have died of phthisis. The urine has a particular odour, which is not perceived by smelling the pot, but if you partly fill a phial with it, and keep it corked for a little time, on withdrawing the cork you may perceive a peculiar smell, something like peppermint. It has also a sweet taste; which you may ascertain by desiring the patient to taste for himself. Generally the urine is clear, and of a lemon-colour. Besides the presence of sugar, there is usually a diseased secretion altogether.

Quantity of Urine voided.—Professor Frank, of Vienna, saw a case in which forty pints of urine were made in a day, on an average; there were sometimes as much as fifty-two pints. He says that other authors have mentioned fifty-two pints being discharged. He also states that he saw a case in which the quantity voided in a very few days exceeded the whole weight of the body. Usually, however, the quantity of urine discharged is from six to twenty pints *per diem*. On the other hand, the urine is sometimes very little increased in quantity, and sometimes not at all. Professor Frank mentions a few cases of the disease where the quantity was not increased, but it contained so much sugar that from two pints of fluid six ounces of saccharine stuff were obtained. One patient of mine made at last but three pints of urine in a day—which was less fluid than he drank. Dr. Heberden mentions a case in which the urine made was double the quantity of the fluid drank. Such are the varieties as to quantity.

Quantity of Saccharine Matter.—In regard to the quantity of saccharine matter, Dr. Dobson procured an ounce of saccharine extract by evaporating a pint of urine. Cruikshank obtained three ounces and a quarter from thirty-six ounces troy, and found the specific gravity to be 1.010. From ten pints of urine he obtained a pound and a quarter of solid extract. Dr. Prout, from a pint of urine, the specific gravity of which was 1.050, obtained two ounces of thick stuff; and from this he

procured one ounce and a half of sugar. Frank says, that from twenty-four pints of urine he obtained twenty-six ounces of saccharine extract. The sugar obtained from urine is like that procured from grapes.

Fermentation of the Urine.—From the presence of sugar, the urine undergoes a vinous fermentation; so that at a certain time, if it be thrown into the fire, it burns as if you had thrown in so much spirits. Still later the urine becomes quite sour. The usual changes go on which sugar is capable of producing—that is to say, you have vinous and acid fermentation.

Urine deficient in the usual Salts.—These are not, however, the only circumstances in this disease, for there is frequently but little urea in the urine—little lithic acid, and little of the usual salts; not that they are absent, for I saw them all myself in the patient's urine which contained such a large quantity of sugar. But it is said that in general they are very deficient, and deficient in proportion to the quantity of sugar formed.

Specific Gravity of the Urine.—As to the weight of the urine in this disease, it depends upon the quantity of sugar; and the quantity of sugar is such as to augment the weight very considerably. Healthy urine is generally of the specific gravity of 1.010 to 1.018; but diabetic urine is from 1.030 to 1.050, and I think I have seen it above that;—and this excessive weight depends upon the presence of sugar.

Hypothesis as to the Sugar being dependent on the deficiency of Urea.—It has been supposed that the sugar is dependent upon the deficiency of urea; and urea and sugar, you know, contain the same quantity of hydrogen exactly, but the quantity of carbon and oxygen in sugar is twice that in urea. It has therefore been supposed that there is only a morbid change undergone in the composition of the urine—that instead of urea you have sugar. However, this is certainly not accurate, because I have seen a large quantity of sugar in the urine where there was likewise a considerable quantity of urea: still, in proportion as the one is deficient, the other is frequently abundant. It is by no means I think proved that sugar is merely altered urea; and those have mistaken the matter who say that urea is absent in diabetic urine, for sometimes a large quantity of urea is found in true diabetes, where of course there is a large quantity of sugar.

Albumen precedes the re-appearance of the Salts.—Dupuytren and Thenard assert that before the salts and urea appear again, if the disease take a favourable course, albumen is found. Dr. Prout mentions that the worst form of diabetes is where the

urine is albuminous—where, besides sugar, you find albuminous flocculi in the urine. In a fatal case of mine, not long before death there were albuminous flocculi, and these flocculi increase the fermentation which the urine experiences from the sugar.

Condition of the Blood.—Now it is pretty certain that no sugar is found in the blood of these patients. Dr. Prout, who is very nice in his examination of these things, says that he has sometimes seen something like sugar, but as for true sugar being found in the blood, it has been looked for by a large number of chemists, but in vain.

The blood sometimes in this disease is of an unnatural appearance: it is said by Dr. Watts, of Glasgow, to be a little like treacle, and of a bluish colour; but this is not an invariable circumstance, for I have not noticed it myself: but it is asserted by Dr. Watts, who, I dare say, may be depended upon. The serum of the blood had a white fluid swimming upon it, and the blood was buffed. I mention this to shew that you may have these things while the urine contains sugar: there is no connexion between them, only the presence of one does not exclude the possibility of the other. I may mention that Vauquelin found no sugar in the blood of a person whose urine actually contained one-seventh part of sugar: he also says that he found no urea in the blood of this individual, though he gave him a large quantity by the mouth for some days. He also states that an opposite occurrence takes place here to what is observed in scurvy, namely, that the blood will not putrify so soon as in health. In one case of my own, and which I believe was the only case in which experiments were made, it was found that the more sugar the urine contained, the larger was the quantity of carbon discharged from the lungs.

Duration and Terminations.—Now this disease may last many years, and it may prove fatal by phthisis; that is to say, it may induce phthisis, or be followed by it. Express the fact in any way you choose—diabetic patients frequently die phthisical. They sometimes die from mere exhaustion, occasioned by the disease, and sometimes they die suddenly; but the most common terminations are by phthisis or mere exhaustion. It may destroy a patient in a year or two, or it may remit, and I believe it may cease, or be cured. Dr. Gregory used to say that he knew a case where the saccharine quality of the urine ceased in two days, and did not return; but whether the observations were made with all the accuracy that we require in modern times, I do not know.

Decline of the Sugar and the Quantity of the

Urine.—Usually the appearance of sugar and the excessive quantity of urine decline together; that is to say, that in proportion as the quantity of urine becomes less, so does the proportion of sugar. You may have the quantity of urine diminished, and yet the proportion of sugar to that quantity remain the same; and on the other hand it is asserted, (but that I have not seen,) that the sugar sometimes diminishes in absolute quantity, while the urine remains in the same excess as before. As, however, the sugar absolutely lessens—so do the salts, the lithic acid, and the urea, generally increase. The colouring matter of the urine is usually deficient as well as the lithic acid and salts, and sometimes the sugar entirely disappears before death. I have in diabetic patients seen the urine suddenly cease to have a particle of sugar in it, and yet the patient has died in the course of three or four days.

Morbid Appearances.—Now after death you will frequently find no morbid appearances whatever. I have several times opened diabetic patients, and as far as I could judge I have found the whole of the body sound throughout. The kidneys have sometimes been enlarged a little, sometimes a little redder or fuller than natural, and a little flabby, but that has been all, and sometimes I have not even seen that. The ureters are said sometimes to be florid; but certainly morbid anatomy only gives you no explanation of this disease. Suppose you see the kidney fuller or larger than natural, and the vessels rendered more distinct, why that is nothing more than you would expect from the kidney being stimulated to excessive action; and whatever may be the cause, that certainly does not explain the saccharine quality of the urine.

Not confined to Adults.—This disease is by no means confined to adults, for it frequently affects children also, but it is not so easily observed in them.

Predisposing Causes.—Diabetes occurs much more frequently in men than in women, and it occurs much more frequently in some countries than in others. Professor Frank says that he saw but three cases of it in Germany for twenty years, and when he practised in Italy he saw but seven cases in eight years. There are far more cases of it in Edinburgh than in London. When I was a student in Edinburgh, there were always some cases of it to be found, but I do not recollect having a case in London for two years.

Exciting Causes.—It is produced sometimes by grief; certainly I have seen it produced by the long continuance of the depressing passions. It is sometimes occasioned by chills—by the exposure of the

body to heat and cold alternately, especially when the body is in a state of perspiration. It sometimes appears to arise from strains of the loins. Whether whiskey has any particular power in producing it I do not know, but it is far more common in Scotland than in England. I suppose they drink as much whiskey in Scotland as in Ireland, but whether the disease is equally prevalent there I do not know. Dr. Latham says that he has seen the disease come on after boils; and I have heard others, I think, confirm the observation. Excess of venery appears likewise to be a cause of it. Some authors mention this most decidedly as a cause of the disease, and in some instances I have asked the question of young men, and they have replied that they had indulged to great excess. Whether they had or had not I cannot say, because people feel differently as to what is excess. I however saw it in one man who had committed no excess of this kind, for he said he had never known a woman, but he died of the disease, and it is very possible that he had committed excess of a less creditable kind. I rather think this was the case, from the great length of the prepuce. Sometimes there is no evident exciting cause at all, and in some cases it is evidently constitutional and hereditary. One German writer mentions seeing seven cases of the disease in one family. Dr. Gregory said that he saw three cases in one family; and Dr. Prout knew a mother, an uncle, a brother, and a sister, all affected with the disease.

Diagnosis.—The diagnosis of the disease is easy enough. It may be made by measuring the quantity of fluid, by weighing it, and by analysing it. You find in diabetes a brown treacly extract, which, on tasting, you find to be sweet. No one can object to taste it, for it is not urine, but sugar. When the fluid is evaporated, there is nothing but hard-bake left, which tastes just as well as any other hard-bake. But although the disease is easily enough made out, if you suspect its existence, and it really does exist, yet it is a disease which is continually overlooked. It comes on so insidiously that many persons have it for a length of time before the medical attendant suspects its existence. The patient complains of being weak and languid, does not know what is the matter with him, and the quantity of urine may not be such as to attract his attention; so that no light is frequently thrown on the disease. I have known so many cases of this kind passed over, that when I see a patient complaining of weakness, and can discover no evident cause, I always question him as to the quantity of urine. Not long ago, I saw a

patient who must have had diabetes for some years; but that circumstance never struck my mind. He had disease of the heart, which was killing him, and it was not till I saw him three or four months afterwards that he spoke of the quantity of his urine. The disease of the heart explained every symptom of which he complained, but upon being told that there was something wrong in his urine, I evaporated a portion, and found it was diabetic; and he then stated that he had made an excessive quantity of urine for several years. No disease is more easily passed over, unless the patient chances to mention that he makes a larger quantity of urine than usual. When you see a patient emaciated, complaining of thirst, with a good appetite, and his skin is dry, and you can see no reason either in the chest or abdomen for these symptoms, it is well always to inquire into the state of the urine.

Pathology.—As to the real nature of the disease, some declare it is situated in the kidney, others that it is situated in the stomach. Now many of the symptoms are as easily explained on one supposition as on the other. Many of them are referrible altogether to the discharge of fluid. The thirst and the dryness of skin are evidently referrible to the loss of fluid. So, again, the costiveness, the emaciation, the hunger, the debility, the sensation of sinking at the stomach, are all referrible to the mere loss of so much substance as must be lost in the production of sugar. But the absence of sugar in the blood, and the very frequent absence of dyspepsia, or any thing connected with the stomach, except the hunger, (which the excessive loss will explain,) make it appear to me most probable that the disease is situated in the kidney.

Perhaps this is the most singular disease in the animal economy; for the nature of it is not known, and the treatment which is found useful is as singular as the disease itself: the remedies are directly opposite.

Treatment.—There can be no doubt that repeated venesection has lessened the symptoms very much, and it is sometimes borne remarkably well. You will find a sufficient number of cases on record, to establish the fact that bleeding is occasionally very useful in the disease; not bleeding to syncope—not violent bleeding—but repeated bleedings, from eight ounces to a pint. I have employed this, and seen it borne in a remarkable manner. In many cases the urine diminished and the quality improved while venesection was going on; but though there can be no doubt of its use, yet it has frequently failed. Some prefer the application of leeches to the

epigastrium, and some cupping on the loins.

Then, again, stuffing the patient with rump steaks (which is a practice directly opposite to bleeding) has also answered as good a purpose. Many persons have their urine improved by being confined to animal diet, having nothing but meat; but still one would imagine that this would not go to the root of the complaint, wherever it may be. It is like giving phosphate of lime in softness of the bones, and taking carbonate of soda to remedy acidity of the stomach: it is merely alleviating, not curing the disease. But you will find it the most difficult thing in the world to make a person adhere to animal diet; he becomes so disgusted with it at last, that he says he would rather starve than eat meat every day. I never found a patient able to continue it for a length of time; still, as there is great weakness, it may be well to make a patient live on meat as much as possible, and you will find as strong evidence in its favour as in that of bleeding.

Then there can be no doubt that opium has a great power over the disease: it increases the quantity of lithic acid, the quantity of urea, and lessens the sugar. I have seen this proved over and over again; nay, so great is its influence, that a very great quantity will diminish the urine as rapidly as it will diminish the sugar in the urine. I once, finding a man dying of the disease, gave him opium so freely that it induced stupor and some degree of delirium; and in the course of sixty hours, the quantity of urine was reduced from eight pints to two in the 24 hours, and from being very heavy it lost the greater part of its morbid specific gravity, and absolutely lost the whole quantity of sugar: indeed urea was produced in excess—the urine contained more urea than it ought to do in health. The man died a few days afterwards of phthisis, but the quantity of opium produced the effect I have stated. In general, by giving opium, and by increasing the doses, you lessen the amount of urine and likewise the quantity of sugar. Of course, in this disease the opium may be increased as it may in any other, and one man who began with half a grain three times a-day, at last took as much as two scruples regularly three times a-day; and it never confined his bowels, which it usually does where patients take a large quantity. His urine became natural; when, through a mistake on the part of those who made up the prescription, he had forty grains of blue pill, which he took three times a-day. Thus there was an absence of the opium and the presence of a strong purgative—a strong mineral poison; and instantly the sugar was brought back into the urine

in the original quantity, and the urine also was increased as before. The opium was renewed again, but I never made an impression on the disease afterwards. Whether the benefit would have continued I do not know; but the urine became healthy, the mistake was made, the patient fell back, and I never made the slightest impression by the same dose of opium again.

It is said that other narcotics answer as well as opium, but I am not aware whether that is the case; however, I have never yet cured the disease even by opium—at least, I am not certain of it. There was one man who, by repeated bleedings, appeared cured; but I did not see him afterwards. By opium, however, by animal diet, or by any other means, I do not know that I ever cured a case. I dare not say that the man was cured in whom the repeated depletions were had recourse to. Of course I am speaking of saccharine diabetes, for as for diabetes insipidus, that may be effectually removed.

The steam bath and the hot bath have been strongly recommended; but I confess that I have used them without any material benefit. Iron has also been recommended, particularly the phosphate; but I employed the carbonate, and it appeared useful, but I have never seen it cure the disease. I have not had sufficient experience of the disease in children, to say whether it may be cured. I saw a child about two years ago making an excessive quantity of urine, and I think it was said to be saccharine; but this only lasted a few days. I will not take it upon me to assert that the disease is never cured in children. Alum, catechu, and astringents, are said to be of service; and it is alleged that they have sometimes cured the disease. But what I would recommend, if the patient's strength would bear it, would be venesection, and a confinement as much as possible to animal diet; and there is no reason why you should not give opium, and at the same time phosphate of iron. These all act in a way that we do not understand; we are not sufficiently acquainted with the disease to say that they will not do good; and if I found a remedy serviceable, I would recommend a patient to use it. It is right always to make a patient wear plenty of clothes, to keep the surface as warm as possible. Warm clothing, and exercise to sweating, have been recommended; but I have known persons perspire profusely in the disease, without any good being done.

NOTES OF LECTURES,

BY THE LATE

DR. JAS. GREGORY, OF EDINBURGH,

On Dyspepsia, Hypochondriasis, and Chlorosis:

Taken in Short-hand, in the years 1819-20,

BY EDWARD BLACKMORE, M. D.

Resident Physician in Bath.

A WRITER in the London Medico-Chirurgical Review for June 1821, at page 218, has stated that "the immense mass of medical information which Dr. Gregory possessed, has perished with him; for the notes taken by his pupils are not only defective, but devoid of all his practical illustrations. His lectures, besides their intrinsic merit, as the vehicle of sound medical learning, were characterized by a richness of illustration quite unprecedented." This remark may serve to enhance the value of the present communication, which, it is presumed, contains ample evidence that *all* the notes taken by the pupils of that great physician, are *not* defective.

His lectures indeed may be regarded as defective in relation to the refined pathology of the present day, which Gregory probably too much neglected:—their style and arrangement also, in their original delivery, were discursive, careless, desultory, and irregular: they were never written by the author, but delivered *memoriter*, from brief notes; they contained frequent and prolix repetitions (which, however admirably suited to oral instruction, are tedious in a written composition.)—but there is no fact in them not worth repeating; their matter is invaluable: for extent and variety of illustration, for the precision and authority of the practical precepts contained in them, they are unrivalled; and on the remote *exciting* causes of diseases, in particular, which the author regarded as an important guide in practice, they are most copious and instructive.

For the cautious scepticism, the candour, decision, comprehensiveness, precision, independence, perspicuity, and vigour of his practical judgment, Gregory was second to no man in any age or country.

They who have had the privilege of having been his pupils, will recognize in the present outline a faithful narration of the facts derived from his transcendent experience; the order of some of the sentences is merely transposed, so as to bring into a combined view all his remarks on the same topic; and a few connecting or explanatory words of the reporter are added, which will be found inserted in brackets.

The consideration of the organic diseases of the stomach is not included in these lectures; the proper subject of them are the adynamic and spasmodic affections of this organ, designated in Cullen's Nosology, which Dr. Gregory made his text book.

In lecturing he seems to have arranged his matter under these distinct heads:—1st, the history and explanation of the symptoms; 2d, the antecedent, coincident, and consecutive morbid affections (generally a mere enumeration of the symptomatic species of diseases noted by Sauvages and Cullen;) 3d, prognostic observations; 4th, the remote causes, and a brief allusion to the proximate causes; but in general he gave up the investigation of proximate causes, (See *Conspectus*, p. 25, 6th edit. Edin. 1818;) 5th, treatment.

SECT. I.—*Comments on the Symptoms.*

First, the *primary* or *essential* symptoms; the definition from Cullen, "Anorexia, nausea," &c.

(a) *Anorexy*: want of appetite is not universally found; the powers of digestion may be impaired, yet the appetite entire; the patients indulge it.

(b) *Nausea*, which produces vomiting; an inverted motion of the stomach, which brings into action the diaphragm and abdominal muscles, produces it: nausea may continue without vomiting, and this occurs without nausea preceding it. There is also an inverted motion of the duodenum in vomiting; *e.g.* the first mouthful vomited in sea-sickness is bilious; it comes from the duodenum: the same thing happens from an emetic, if long continued, and even sometimes in the first effort to vomit: this is bilious vomiting, which is not the cause but the effect of the disease. Instantaneous vomiting will occur from matters irritating the stomach, as Sulphas Zinci. Under this symptom may be placed pyrosis, or water-brash: there is cardialgia, and spitting up of insipid or sour watery matter. All my patients had other symptoms of dyspepsia with it. Dr. Cullen thought it was a spasmodic affection of the small vessels of the stomach; this would account for the insipid matter, not for the acid water thrown up, which must be from fermentation of the matters taken in, (and also from the secretion of acid by the mucous membrane.—E. B.)

(c) *Inflation*: there is flatulence from fermentation of the mass taken into the stomach; some peculiarity occasions flatulence, and the food most easy of digestion may ferment. Distention of the stomach gives uneasiness (anxiety), not pain, but oppression about the præcordia. The stomach is weakened from the distention, and still more from the acidity in it; hence

dyspepsia prolongs itself. Sometimes there is a putrid colluvies, like the smell of rotten eggs, or *hepar sulphuris*. There is a swelling of the præcordia, so that the patient cannot button the waistcoat; the stomach is distended; but the patients exaggerate; they say it is from wind. (Gas also may be secreted by the vessels of the stomach, without fermentation of the food. See Magendie's Physiology, for the nature of the various gases.—E. B.)

(d) *Ructus*, eructation; a discharge of flatus and other matters, which may be sweetish, acid, putrid, or bilious: it is done by the contractions of the stomach itself, (or a voluntary action of the gullet and abdominal muscles, E. B.) Sometimes in endeavouring to blow (wind instruments), air is swallowed, and the stomach is distended: this influences the action of the organ; it is a bad habit. *Ruminatio* sometimes is met with, (a variety of eructation), a bringing up of the half digested aliment, chewing it, and again swallowing it. (*Singultus*, which might have been considered here, was omitted by the lecturer.)

(e) *Pain*; 1. *Cardialgia*, from acid or alkaline matter in the stomach; the acid matter is applied at the cardia, or upper orifice of the stomach, which gives that burning pain; (it is different from the next variety of pain, the mucous membrane is here the seat of irritation;) the patients describe it as "a pain of the breast;" they are inaccurate about the seat of their diseases. There is a pain in the breast also, from sympathy between the stomach and the muscles of respiration.

2. *Gastrodynia*: people are almost convulsed and delirious from the terrible pain; it is from a spasm of the (muscular and nervous) fibres of the stomach, and also from acidity; (a neuralgia also of the semilunar ganglia of the sympathetic nerve.—E. B.)

(Such are the essential symptoms;) the same patient has not, however, all the above symptoms.

Second, the *occasional* and *secondary* symptoms; the coincident or consequent affections of various organs.

(a) Disorder of the head and nervous system.

People first become hypochondriacal, afterwards melancholic and deranged. "Hypochondriasis occurring only in the melancholic temperament, always with dyspepsia."—CULLEN.

There is a great connexion between stomach complaints and low spirits: there is distortion of the mind; anxiety about the health; such patients are said to have "black eyes, black hair, and to be of a thin, spare habit;" this is the physiognomy of the melancholic temperament; but the

disorder also occurs in others who are not of this temperament. The symptom is not inseparably connected with dyspepsia; some persons get hypochondriasis and mania without indigestion; and some things which are good for the dyspeptic are bad for them. I have seen hypochondriasis in the sanguine temperament.

There are many symptoms referred to the head in dyspepsia; head-ache; the head is heavy, oppressed, with a sense of weight or vertigo, and a violent ringing in the ears; depravation of sight; the patient sees various colours, flashes of light, spangles, from the state of his stomach. There is also urgent pain of the eyes: it is inexplicable; an ultimate fact.

Hysteria is sometimes a symptom: many of the hysterical are dyspeptic, the disorder of the stomach is the predisposing or exciting cause. There is no regular proportion between dyspepsia and hysteria. The rumbling noise (in the belly) is thought to shew a disturbance in the course of digestion.

Other spasms also occur, as transient pains about the sides and limbs; the feeling is like that of spasm; it is no inflammatory affection, but connected with flatulence in the stomach; from a discharge of flatus, the pains go off.

Cramps in the legs also happen from disorder of the stomach; a bilious purging also occasions these cramps.

(b) Affections of the heart and blood-vessels.

Pains are referred to the region of the heart, "pain in the breast," with palpitation of the heart, and intermission of the pulse; the patients feel uneasy at the instant; they think they are going to die. People will come complaining of disease about the heart: you find it arising from disorder in the stomach; *e. g.* from seasickness the whole body is shaken. I had palpitation of the heart from it for many hours. Remember that disorder of the stomach will in some persons produce intermission of the pulse. The stomach is distended by its (fluid) contents, or by flatulence, which presses the diaphragm upwards; the stomach is thought to rise as high as the fifth rib; it presses on the heart; yet the palpitation is not always from that mechanical operation. (The nervous relation of the heart and stomach is shewn in that) before the food shall have been digested, it will restore the heart's action like wine, in cases of exhaustion. On the discharge of flatus, the palpitation ceases, or on spitting up the undigested, acid, bilious matter.

(Pulsation of the abdominal aorta, which is sometimes so severe and so perplexing in the dyspeptic, was omitted by Gregory.)

(c) The respiration also is impeded from

dyspepsia, or from any load of the stomach, as from meals which are difficult of digesting: no one can run well after a full meal; it has produced urgent dyspnoea. Eating salmon would bring on spasmodic asthma in a certain case; so will a full meal. The muscles of respiration are brought into spasmodic action from the irritation of indigestion. [See below, Sect. III.]

(d) Affections of the liver are produced by long nausea and vomiting; the biliary ducts are emulged, the secretions increased; bile is brought up into the stomach from an inverted action of the duodenum, which again gives rise to nausea, vomiting, and pain; a bilious purging and jaundice are also occasioned; the perspired matter is yellow; it tinges the linen. The bilious habit remains for years; that is, there is a vitiated or too copious secretion of bile. It is the effect of dyspepsia. On the other hand, morbid affections of the liver will cause indigestion. [See below.]

(e) Disorders of the alimentary canal.

The state of the mouth is to be attended to:—1. Sometimes it is morbid, dry, with thirst. The tongue is white, foul: it is an index of the state of the stomach, it being a part of the same canal. Dryness of the mouth shews a want of secretion into the stomach; (sometimes, but not always, this is from an erythematous state of the mucous membrane.—E. B.) A viscid, mucous tongue, shews a viscid state of the secretions in the stomach.

2. Salivation co-exists with dyspepsia: it is analogous to a viscid secretion of fluids into the stomach, as is shewn by the quantity of mucous fluids which are vomited; the vitiated mucus is quickly collected again.

The belly is generally costive.

People sometimes, however, have a purging, alternating with costiveness; a purging is succeeded by torpor of the bowels.

(f) Sometimes the kidneys are affected; the secretion of urine is disordered.

The disposition to gravel (*lithiasis*) is connected with the state of the stomach, with acidity. The most common base of calculi is uric acid, from the acid of vegetable matters, which are undigested.

(g) Chlorosis, (*anæmia*), "paleness, sallowness, weakness, sighing; it is symptomatic from want of the menses, but not always;" (and the amenorrhœa is a part of the more general disorder, rather than its cause: the stomach is first and chiefly deranged.—E. B.)

(h) Gout, which is an inflammatory disease in the hands and feet, will arise from disorder of the stomach; its connexion with dyspepsia is to be attended to in practice. Gout is not produced in young people by dyspepsia, except where it is

hereditary; then they have gout after indigestion. It is the cause of the gout; for this comes on after taking acescent wines, as claret. Gout was thought formerly to be from an acrid morbid matter in the system. People, who were thought to be dying, suddenly got rid of the symptoms on getting a fit of gout.

SECT. II. — *The Symptomatic Species of Dyspepsia, or the antecedent affections.*

(A) Of the stomach itself.

(These states are organic causes pathologically regarded, and might be properly considered in the section on the pathology of the disease.)

Scirrhusity is produced in different parts of the stomach: people have had scirrhus of the stomach in the decline of life from (idiopathic) indigestion at a former period. There was in such patients vomiting of blood, with suppuration, abscesses, &c. In the case of a scirrhus pylorus, the consequence is a detention of the aliment, which produces the definitive symptoms; a total want of proper digestion, and a vomiting of the matters, even before you can feel the swelling: vomiting occurs in this case generally two hours after taking food. The weight of the tumor will pull down the stomach; you can feel the pylorus below and to the left of the navel; Morgagni says, it has been felt just above the pubes. I have seen it fixed there by adhesion.

There may be suppuration in the stomach after inflammation: some recover, others linger and die. In this case there is hectic fever, and great disorder of the functions of digestion. In one case there was urgent thirst, as in a fever, from a morbid state of the stomach: the mouth was very dry.

(B) The function of the stomach is also disordered by disease in other parts.

(a) From ulceration of the intestines, there are slimy, bloody stools, and the contents of the bowels are even thrown upwards; the stomach becomes severely affected; there is occasionally no pyrexia.

(b) Also from disease of the liver, if it is inflamed, or suppurated, or swelled, or hardened; sometimes, indeed, it is shrunk in bulk. We not unfrequently feel the swelled liver in the left hypochondria; you can trace the swelling into the right hypochondria. Inflammation of this organ is often chronic; it will last for months, with indigestion almost universally. In a case that quickly died, (which I thought was idiopathic, but it was symptomatic,) the liver was diseased; large pustules*

* (Here is an instance of the then imperfect state of morbid anatomy: these supposed "pustules" were tubercles and puriform hydatids.—E. B.)

were seen over the surface of the bowels and peritoneum.

People suppose that a superabundant quantity, or deficiency, or acrid quality of the bile, is the cause of indigestion; whence come these morbid states of the bile? Various morbid conditions of the liver do indeed affect the stomach and cause indigestion. People become dyspeptic from an overflow of bile in hot weather, as in the East Indies, (and from the effect of mercury, E. B.) This happens independently of previously existing dyspepsia.

(There are also paroxysms of biliary *epischesis*, or suppression of the action of the liver, which occasion stomach disorder: the stools are clay coloured.—E. B.)

The bile may be vitiated; sometimes it is black like tar: I know not what it is that gives it that colour. It is absurd to apply to our climate what is peculiar to hot climates, (except in similar seasons and states of the atmosphere.—E. B.)

(γ) There is nausea and bloody vomiting from disease of the spleen.

(And of the spleen also, which was little noticed)

(δ) Dyspepsia also occurs from a stone in the pelvis of the kidneys; the stomach is weakened (sympathetically,) and the patient is dyspeptic from the nausea.

(ε) From uterine affections:—

(1) In pregnancy, there is nausea and vomiting.

(2) Morbid states of the uterus will cause indigestion:—

(a) From a want of the menses at the time they ought to flow, in chlorotic girls (*amenorrhœa emansionalis*) there is weakness of the stomach; failure or depravation of the appetite; impaired digestion.

(b) In suppression of the menses from exposure to cold, wet feet, emotion of the mind, irregularity in diet: there is a loss of appetite, nausea, and vomiting, from the first, or soon afterwards; the skin becomes hot, headache and vomiting ensue, or hæmorrhage from the lungs.

(c) An overflow of the menses, or leucorrhœa, is also connected with dyspepsia.

(I have also seen obstinate dyspepsia from sexual disorders in the male; which Gregory omitted to notice.—E. B.)

(5) Loss of appetite, nausea and vomiting, are, moreover, symptoms of apoplexia hydrocephalica.

(η) Disorder of the stomach likewise arises from the improper repulsion of external diseases (lichen, herpes, lepra, and ulcers.—E. B.)

SECT. III.—*General Observations, referring to the Course and Prognosis of the Disorder.*

Duration and Danger of the Disease.—A fit of dyspepsia sometimes occurs as a fit of

syncope. This transient indigestion is produced by slight causes; when induced, quickly or slowly, it may continue for days, months, or years. It is not dangerous. The symptomatic disease from an organic affection of the stomach, liver, or spleen, is generally fatal at last. You may see, however, thousands who do not die. They generally exaggerate their sufferings. Pyrosis is very hard to cure; it will continue for years, in spite of all our remedies. The disease often lasts long without disorder of other functions, except that the spirits are depressed. Dyspeptic people may have good strength—may have even a fresh colour; others have appetite, although their digestion is slow and imperfect: they take in more food than they can digest, yet enough is digested to supply the waste of the body.

Effects.—If indigestion is of long standing the health suffers; there is weakness, paleness of the face, flaccidity of the muscles, softness of the skin. The state of the solids is the same as in rickety children: the fat is absorbed, there is a wasting of the muscles, and morbid tenuity of the blood. I do not believe in its morbid spissitude; I do not like the humoral theory; but there is a morbid tenuity of the blood in dyspepsia—it has not the usual dark-red colour. There is a laxity of the solids, a tendency to leucoplegmasia and anasarca, or general dropsy: the patients have died dropsical. Hætic is produced, they say, but is not a common occurrence; indeed very rare (that is in idiopathic dyspepsia): they have then some other disease with the dyspepsy—e.g. disease in the lungs, &c. Do stomach complaints lead to, or preserve from, phthisis? They used to think the dyspeptic not apt to become phthisical; as those with acid eructations were said to be not liable to pleurisy: but certainly they do not preserve from phthisis. I have seen dyspepsia with phthisis in hundreds. The hætic from tuberculated lung is mistaken as if it was hætic from dyspepsia. (There is hætic from cancer of the stomach in the ulcerous stage.—E. B.)

Prognosis—Sanability.—A case. One suffered much pain at the stomach, and was relieved by antacids and opiates. A blister had been applied, to no purpose. There was a suppression of the menses also. Hæmatemesis followed. By attention to the general health she recovered, and is in good health now—twenty-eight years after! There was a degree of suppuration: the erosion (ulceration) of the organ gave rise to the vomiting of blood.” (Dr. G.’s pathology of this case is very doubtful: but cancer of the mamma may cicatrise, and why not ulcers of the stomach? See

Abererombic for cases of dyspepsia which resembled the organic affection, but were cured by tonics and purgatives.—E. B.)

(On the foregoing history of dyspepsia, it may be remarked that Gregory is defective in generalization: he does not give the various pathological forms of the disease—e. g. (a) one form is seen in the aged, consisting of an affection of the secretory and muscular function, with pain: it often passes into organic disease. (b) Another form in the young female, with anæmia and amenorrhœa, pathologically similar to the former: a spasmodic disease. (c) A third species is found in the young of both sexes, from inflammatory or congestive irritation of the mucous membrane—gastritis erythem. chronic; but devoid of the ordinary symptoms which characterize inflammation of the stomach. Probably there are only two anatomico-pathological species: 1. A disorder of the muscular or contractile function of the stomach—a debile or nervous state. 2. A disorder of the mucous coat and the secretory function—a spasmodic and congestive state.—E. B.)

SECT. IV.—*The remote exciting Causes.*

Sometimes, indeed, none are discovered.

(1.) *Strong drink.*—Strong malt liquors and the free use of wine, or, worst of all, distilled spirits, in whatever quantity, pure or diluted, ultimately injure the stomach, and will have a bad effect on the constitution.

I inquire of my patients, "What kind of liquor do you drink?" I get hundreds of dyspeptic patients to confess that they take spirits: "only the best of whiskey," is the reply. People, on taking "toddy," are sick and languid the next day. The bad effect of the poisonous beverage is not felt in a minute, but in a few weeks. Water only is provided by nature: all its votaries flourish! I never got a patient by water-drinking, but thousands by strong liquors! The hands of drunkards become tremulous—they get dropsy from diseased liver. Water is often impregnated with other matters which afford nourishment, by infusion and decoction: as toast-water, water-gruel, rice-gruel, sage-tea (which is an old drink), barley-water, &c. &c.

Water is also impregnated by fermentation. Scotch small-beer is laxative, but ale and porter will intoxicate and hurt the stomach: many get stomach-complaints by it. Small-beer keeps sailors from the scurvy; but it is unnecessary if you get fresh vegetables. Fermented liquors are used to counteract the bad effects of animal food.

Obstinate dyspepsia is induced by the long and free use of wine: it is not generally pure; people mix brandy with it.

See Brande's account of the alcohol in wines: in Madeira there is a twenty-fifth! Strong liquors weaken the stomach vastly: drunkards are dyspeptic. People enjoy good health without wine; it is no more necessary to a Christian than to a Mahometan, nor to a man than a horse! All strong liquors are unnecessary; when taken largely, or habitually, the bad effects are inevitably perceived; they give an unnecessary stimulus to the stomach, but a "drain" may digest a heavy dinner, which, without it, could not be digested: they will pay dear for the benefit if the practice is continued. In fermentation there is intestine motion; swelling and sourness are produced; air is extricated—it would burst a bottle.

(2.) *Unwholesome Meats.*—Fat, vegetable oil, or butter, is sometimes abominably rank (rancid, putrid). People live, however, where they can get nothing but train-oil; as the Equimaux—a tribe found who never tasted the production of the earth: astonishing!

The use of very fat oily food occasions an overflow of bile: butter and pastry are the worst things known (for the dyspeptic). Abstinence from such is highly necessary. An old connexion was observed between roast beef and inflammation of the liver: rich animal food occasions a vitiated secretion of the bile. Oily matters bring on indigestion: what is taken in grows sour; the patients will spit mouthfuls of oily matter; the oily part of the aliment remaining undigested, it makes the digestion of other matters imperfect and slow. Putrid animal food (as game) occasions dyspepsia.

Eating salmon would bring on spasmodic asthma from the indigestion, in a certain case.

Raw aceescent vegetables—sallad, radishes—are bad: they dissolve slowly in the stomach. Many eat the lettuce when well boiled, but if raw it is bad. Some cannot take ripe fruits; which are the only article I allow the dyspeptic without a process of cooking.

A Discursion on Dietetics.—Farinaceous matters, rice, barley, oats, afford much nutriment. Saccharine matter is obtained from vegetables, their nutrient roots and leaves, and from fruits which are the lightest and least nourishing substance: the date, fig, and grape, are articles of food. The expressed oils of vegetables, butter, and oil of olives, which is used in warm climates, afford much nourishment. Maccaroni is the paste of flour and water; it is softened by coction in water. Various roots are used: the farinacea-cabbage is said to be strong food, not easy of digestion; cauliflower and broccoli are nourishing. Ripe fruits contain saccharine mat-

ter: they form a spare and cooling diet. All are intended for the nourishment of mankind.

No mineral substance affords nourishment. Sea-salt is a condiment—it promotes digestion. The free use of acids will disorder the stomach; but vinegar and aromatic sulphuric acid were thought to strengthen it.

Animal substances are more nourishing than vegetable: a smaller quantity of such than of other food will supply the waste of the body. In making soup, what remains affords no nourishment: greater nourishment is got from solid animal flesh. Some people live on animal food alone, in the rancid, putrid state (as the Esquimaux); others live only on vegetables, as the Hindoos—some of whom will not eat even fish—using merely a quantity of aromatics as a kind of butter; and they who use a small quantity of animal food with their rice are not stronger or larger than the others. Animal food alone is too great a stimulus to the stomach, as is too great a quantity of distilled spirits. Nature intended us to live on both animal and vegetable food; a proper mixture of such food is to be made.

CASE OF CYANOSIS;

WITH AN ACCOUNT OF THE MORBID
APPEARANCES.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following notes of a case of cyanosis of sufficient interest for the pages of your journal, you will oblige me by their insertion.

The subject of this disease was John Thomas, of Waleote, Leicestershire, aged nearly 4 years. I had been in the habit of seeing this child occasionally from his birth: he appeared as healthy as usual till towards the end of the first year, when his lips, fingers, and toes, were observed to acquire a blue colour; his appetite was generally good; and, with the exception of those blue parts of the surface, he remained tolerably well for 6 or 8 months longer. About this time his breathing began to be affected, with occasional paroxysms of dyspnoea; and the blueness, which was increased during these paroxysms, became more diffused over the body. He was never competent to any exertion

common to children of his own age; and if he walked a few yards, he was obliged to rest himself on his hands and knees—a position which he usually had recourse to for relief, and in which he had for a long time been accustomed to sleep; and if occasionally he got upon his side while sleeping, he quickly awoke, and returned to this attitude. In the spring of the present year he had the whooping-cough, which of course materially aggravated all his symptoms, but on the whole it passed off favourably. He continued in this state, with little variation, till five weeks ago, when the blueness acquired a more fixed and leaden hue: at this time he became subject to more violent attacks of dyspnoea, attended at intervals with slight convulsive movements and syncope: these paroxysms recurred frequently during both day and night, and as consciousness returned, he went for relief to his usual position upon his hands and knees, or to lie upon his face across his mother's lap: he likewise was in the habit at such times of drinking cold water, which he did freely, and it appeared to afford him some relief. I gave him likewise the following mixture, which seemed also for a time to relieve the most distressing symptoms:—

R Sulph. Quinin. gr. iij., Acid. Sulph.
Dilut. 3ss.; Infus. Rosæ, ℥ij.; Syr.
Mori, ℥ij. ft. mist. Cap. cochl. ij.
min. ter in die.

On Monday morning, Aug. 12, after a fit of the above description, he suddenly expired.

Dissection, 26 hours after death.—The corpse was somewhat taller than usual for a child of four years, and very thin, but presented externally nothing more than common, except the leaden-coloured fingers, &c. There was very little fat, and the muscles were small, but of the usual colour. On opening the thorax, we found the lungs collapsed and of a dark colour; the vessels of the pleura were strongly injected with dark-coloured blood; the pericardium contained about an ounce of fluid; the heart was of a dark colour, with its apex considerably rounded, and the right auricle enlarged and distended. In cutting through the vessels, to remove the heart and lungs, nearly a quart of fluid purple blood escaped from the venous system, which was everywhere very much gorged. An opening was now made into

the right auricle, and here the fossa ovalis presented no opening to our view; but on the probe being passed behind a valvular fold of membrane, which partly covered the fossa, it readily found its way into the left auricle. The left auricle was now opened, and appeared of its natural size, and the remains of the foramen ovale presented a fold of membrane similar to the one in the right auricle, so as completely to shut up the communication between the auricles: this opening was large enough to admit a very small quill. The aorta was considerably larger than its full size; the ductus arteriosus was completely obliterated; the pulmonary artery was contracted to the size of a turkey's quill: on slitting it up, the semilunar valves were found healthy; the contraction of the orifice was situated immediately beneath them. Here also were observed some granulations, which appeared to us to be assisting in obliterating the pulmonary artery: the parietes of the right ventricle were as much as three-quarters of an inch in thickness, and firm; the muscular fibres were more condensed than those of the left, and its cavity much diminished; the columnæ carneæ pale; the lining membrane and tricuspid valves natural; the walls and cavity of the left ventricle were also natural. The finger passed freely from this cavity into the aorta, and on passing the finger of the other hand into the right ventricle, an opening was found in the septum ventriculorum, at the base of the heart, the size of a sixpence, where it came in contact with the finger already passed into the aorta from the left ventricle, and on opening the ventricle rather more freely, the communication was seen between the ventricles at the origin of the aorta. There was no appearance of disease in the aorta, its lining membrane, or valves: the pulmonary veins were rather smaller than natural. On opening the abdominal cavity, the liver was seen of a large size, extending from the right into the left hypochondriac region, and of a dark purple colour; the gall-bladder contained a moderate quantity of well-coloured bile; the stomach was very much contracted and pale; the spleen was much larger than natural, and of a dark blue colour; the kidneys also were congested with venous blood, the emulgent veins being distended. The mesenteric glands were enlarged, as likewise were the glandulæ Peyer.

I much regret that we were not permitted to remove this very interesting malformation.—I am, sir,

Your's obediently,

ROBERT SPACKMAN, M.R.C.S.

Lutterworth, August 24, 1833.

CONTAGION OF ERYSIPELAS.

To the Editor of the Medical Gazette.

SIR,

THE observations of Dr. Ellin, of Newark, on the cases of erysipelas which you did me the favour to publish in your No. of July 20, have only met my eye within the last day or two, owing to my absence from home. Dr. Ellin speaks of my "premises," "lucubrations," and of being "so blindly wedded." These, sir, are certainly not very gentle terms, if called for, or appropriate. What "premises" (signifying propositions antecedently proved) I have ventured upon, I think your readers will be at a loss to discover, as well as myself; and so also with respect to "lucubrations,"—for, according to Dr. Ellin's own shewing, my report was only looked upon by him (as intended by me), in the light of "a brief statement of facts," which same statement, he tells us, has elicited his remarks. And as to my being "blindly wedded," this, I humbly conceive, must also be altogether a matter of opinion. When a man has this accusation laid at his door, for merely recording simple and undisguised facts coming under his own observation, and stating that they are satisfactory to his own mind, surely Dr. Ellin, on consideration, cannot but see the inapplicability of his language. Had I gone over, and, though defeated, pertinaciously and unsubstantially resisted argument after argument with Dr. Ellin, or any other person—or had the facts of my paper been brought to bear upon the opposite side, and to my own conviction—then perhaps, but not till then, should I be justly deemed "blindly wedded" to certain doctrines.

But, sir, let me turn to the marrow of Dr. Ellin's criticisms, which I will dispatch in a very few words. He says, that "had any of the friends of the Parfitt family had the disease, then he would have been convinced that there are instances so palpable, of ery-

sipelas being communicated from one person to another, and that this one fact would have been worth a thousand speculations." Although I am misquoted here by Dr. Ellin, I shall do no more than allude to the circumstance. Now probably (but I write hesitatingly, since the Doctor's appetite evidently does not soon arrive at satiety) Dr. Ellin will be satisfied with the self-same "brief statement," with which he has expressed himself so acutely dissatisfied, if he will but take the trouble to refer to the last paragraph of the oft-mentioned statement. This, however, I will here quote, with your permission, in justice to myself, and likewise to prove to Dr. Ellin that he might have bestowed a little more attention on the contents of the production upon which he has thought fit to display his critical skill. My words are, "One person only, residing in another house in the village, has had the disease, and that was the aunt of the above persons. She was taken ill after No. 2, and had sat up two or three nights

with No 1, and had likewise been much with him by day." After this, I imagine the question is at rest between Dr. Ellin and myself; and there can be no necessity for my contesting with him the ground he has trod upon, of "endemic disease," "agues," "tropical suns," &c.—I beg to remain, sir,

Your obedient servant,

G. BURY.

Farnham, August 24, 1833.

APPARATUS FOR FRACTURES BELOW THE KNEE.

To the Editor of the Medical Gazette.

SIR,

I SHALL now proceed to shew the method which I have used in fractures of the tibia and fibula. The following sketch of an apparatus represents a plan for suspending fractures below the knee;

FIG. 1.

FIG. 2.

FIG. 1 represents an apparatus for suspending fractures of the tibia and fibula.

FIG. 2 represents the application of the

and if properly applied, the patient is enabled to move in any direction. After reducing the fracture, the usual splints for the leg are applied; the limb is then placed on a pillow, or pad, over the plain of the apparatus, and secured thereon by means of a broad strap (c); and the posterior part of the apparatus is secured to the thigh and the pelvis by two straps, one round the thigh (a) and the other (b) round the pelvis. The apparatus is suspended by two ropes to any thing which may be contrived at the top of the bed, or over a couch. An air pillow placed under the nates tends much to the patient's comfort.

The principle is due to Mr. Moyer, a German surgeon; who not only suspends fractures below the knee, but also fractures of the thigh. His plan (which may be seen by referring to his work, published about seven years ago) I think not sufficiently applicable; neither is the motion of the swing so extensive as in the above. I have at this time a patient, an adult, with a compound fracture of the tibia (which happened July 28th) on the apparatus, who has experienced only a very slight catch of the limb on going to sleep; and so trifling is the inconvenience, that he has slept seven hours at a time, and, as a matter of course, the system suffers so much less from local and general irritation—a point of no small importance in the treatment of fractures. In conclusion, allow me, Mr. Editor, to offer you my thanks for inserting these papers in your valuable journal: all I claim is the humble merit of endeavouring to alleviate pain by giving a faithful description of those means which I have found effective in producing quietude in fractures of the extremities.

I remain, sir,

Yours most respectfully,

JOHN GRANTHAM.

August 9, 1833.

Supplemental Note.

Sir,—In corroboration of the utility of suspending fractures of the tibia, I beg to state that the wound of the patient to whom I referred, when I forwarded my last sketch, healed up on the twentieth day. Ossific union is now nearly completed; this being the twenty-ninth day from the time of the accident.

J. G.

Crayford, Kent, Aug. 16 1833.

THE NATIONAL VACCINE BOARD.

To the Editor of the Medical Gazette.

SIR,

IN the No. of the Medical Gazette for the 8th of last June, I have accidentally observed a letter which should not, I think, be suffered to pass without notice; but as none appears to have been bestowed upon it in the subsequent pages of your journal, you will not, perhaps, object to insert the following remarks.

The letter to which I allude is from Mr. Brown, of Musselburgh, formerly an active supporter of the practice of vaccination, but now an open and vehement opposer of it. The writer of the letter *assumes* that “the vaccine discovery stands distinctly convicted of being an uncertain, feeble, and temporary antidote, against the influence of variolous contagion;” the proof of which assertion he declares to be too notorious even to require stating.

I will not stop to notice the inconsistency of this writer in hazarding such broad assertions respecting vaccination, whilst he admits, at the same time, that “a *great activity* of variolous contagion is required to produce *any effect* upon the system,” which is protected by vaccination, even after the lapse of ten years, the period to which he elsewhere affirms that the protecting influence of vaccination is confined.

Neither shall I attempt to answer the inconclusive arguments urged against the practice of *re-vaccination*, as if this expedient must necessarily fail, even when the system is open to an attack of small-pox; although I should consider it far more probable that when re-vaccination fails—that is, as long as the vaccine disease protects the system against a repetition of its own action, so long it should also protect it in some degree against the variolous infection.

But what I chiefly wish to notice is, the unfairness of which the writer has, unintentionally perhaps, been guilty. He calls loudly for inquiry respecting the efficacy of vaccination; he urges the Government to undertake it; and accuses the National Vaccine Board, without reserve, of a neglect of duty. Now, since an inquiry has been instituted by Parliament into the expediency of

continuing the Vaccine Board, which inquiry involves, of course, the question of the efficacy of vaccination, it would only have been fair to have awaited the result of that inquiry. How, if it should turn out that vaccination has been undeservedly decried—that the Vaccine Board has been unjustly accused—that, according to the best information which has been obtained in London, the number of cases in which vaccination, *properly performed*, has failed to protect the system from subsequent small-pox has been small compared with what it has appeared to be, from including cases of imperfect vaccination—that the proportion of fatal cases after vaccination, anyhow performed, has been inconsiderable—and that absolutely not a single fatal case has been discovered after vaccination ascertained to have been regularly performed by any of the vaccinators of the National Institution—if these things should appear, would it not have been manifestly unfair to have thrown out premature insinuations against a Board which has performed its duties faithfully? Would it not have been inexcusable to have harrowed the feelings of those who depend upon vaccination for their own safety, or for that of their friends or of their children, with rash and unfounded assertions respecting the insecurity of their dependence?

And here I must observe, how contradictory are the arguments urged against the continuance of the Vaccine Board. By one party it is contended that vaccination is so universally esteemed, and the practice of it so generally established, that the continuance of the Board is entirely useless. By the other party, that vaccination is worthless, and that therefore the Board should be discontinued. Truly, the Vaccine Board is beholden to Mr. Brown, for shewing how exactly the arguments of one class of its opponents neutralize those of the other, so that the expediency of its continuance must be allowed to remain unaffected by either.

I am, sir,
Your obedient servant,
MEDICUS.

London, August 14, 1833.

ANALYSES AND NOTICES OF BOOKS.

—
“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.
—

Annales d'Hygiène Publique et de Médecine Légale. Tome dixième. Première Partie. Juillet 1833.

AMONG the interesting papers in the present number we will particularly distinguish one by the eminent statistical writer of Brussels.

M. Quetelet on the Weight of Man at different Ages.

The facts in this paper are curious and valuable, both with respect to physiology and forensic medicine. All the researches hitherto made on the subject have had reference to the period of birth, or to the epoch of complete development: little has been done for the intermediate ages. But the great importance of the inquiry relative to the progressive development of man, is evident from the problem, which is often proposed to the medical jurist—to state the age of an individual from an examination of his physical properties. An opinion may be hazarded by an inspector, and his report may be received; but unless he have taken into account the stature and weight of the individual, as well as certain other peculiarities capable of measurement, his opinion is a mere dictum—vague, and destitute of any solid support. The height of man has been frequently examined: the weight it has remained for M. Quetelet to inquire into, with all that exactness of which the subject is susceptible.

As to *new-born infants*, from observations made on 63 males and 56 females, in the Maternité de Saint Pierre, it appears that the mean weight of the former was 3.20 kilogrammes (6.536lbs.), while the length, by Chaussier's mecometer, was 0.496 metres (1 foot, 6 inches, 3 lines); and of the females, the mean weight was 2.91 kilog. (5.923lbs.), the length 0.483 metres (1 foot, 5 inches, 10 lines). Whence it is inferred that at birth there is an inequality in the weight and size of the two sexes—the males having the advantage in both.

Chaussier seems to have been the first who remarked that the infant, presently after birth, begins to lose some of its

weight. M. Quetelet, from seven series of observations, extending in each case to the seventh day, has confirmed M. Chaussier's remark, and shews that the infant does not begin to grow perceptibly till after the first week.

M. Quetelet gives a table of the corresponding weights and statures at the different ages. We extract a few of them, by way of specimen:—

Ages.	Males.		Females.	
	Height.	Weight.	Height.	Weight.
	<i>m.</i>	<i>k.</i>	<i>m.</i>	<i>k.</i>
At Birth	0.500	3.20	0.490	2.91
1	0.698	9.45	0.690	8.79
3	0.864	12.47	0.852	11.79
6	1.017	17.24	1.031	16.00
10	1.275	24.52	1.248	23.52
20	1.674	60.06	1.572	52.28
30	1.684	63.65	1.579	54.33
40	1.681	63.67	1.579	55.23
50	1.674	63.46	1.536	56.46
70	1.623	59.52	1.514	51.51

In order to render these results still more striking, the author has delineated, by two curves, the course which the weight takes in either sex: the ordinates of the curves expressing the weights, and the abscisses the ages. It is thus seen at a glance, that at any given period the man is generally heavier than the woman. About the age of twelve, however, it may be observed that the weights of both sexes are generally equal. This circumstance must, of course, be imputed to the earlier approach of puberty in the female.

Some of the other conclusions of M. Quetelet are curious. Man attains his maximum weight about the age of 40, and begins to lose weight very sensibly towards 60. Woman is not at her maximum weight till towards 50. Between 18 and 40, the period of her fecundity, she does not acquire any very perceptible increase of weight.

Both man and woman, at the period of their complete development, weigh almost exactly twenty times as much as they did at birth. Their height at the same period is about $3\frac{1}{4}$ times what it was at birth.

In their old age, both man and woman have lost 6 or 7 kilogrammes of their weight, and 7 centimetres of their height.

During the growth of both sexes, it may be stated that the squares of the weights are as the fifth powers of the heights.

After the development is complete in both sexes, the weights are very nearly as the squares of the heights: whence it may be inferred that the increase in the height is greater than the transverse increase of the body, comprehending both its breadth and depth.

The mean weight of an individual, without reference to sex or age, is 44.7 kilogrammes (91.336 lbs.); or, if sex be taken into account, it is 47 kilogrammes (96.015 lbs.) for men, and 42.5 kilogrammes (86.831 lbs.) for women.

According to the observations of the late M. Tenon, of the Institute, [which observations are given by way of supplement to M. Quetelet's paper,] the Laplanders and the Patagonians present the two extremes of man's stature. The former commonly measure from 4 feet to 4 feet 6 inches, 4 feet 3 being their mean height, and their women are scarcely less. The Patagonians measure from about 5 feet 6 inches to 6 feet 3, and their women are generally 7 or 8 inches shorter.

The tallest men in Europe, M. Tenon thought, were in Saxony. But he added, that climate or locality had less to do with the stature of men than their race or variety. Close by the Saxons, for example, we find the Silesians, who are a short people; and near the Patagonians are the Pecherai, a people much inferior in height. In Savoy also, and particularly about *La Haute-Maurienne*, extreme varieties have been noticed. Yet it can scarcely be doubted but that the climate, the nature of the soil, the sort of government, the state of civilization, and the comforts, or the contrary, of each people, have much influence in determining a national stature. This position has been strongly urged by M. Villermé, in his *Memoire sur la Taille de l'Homme*; and very interestingly stated by W. F. Edwards, in his *Caractères Physiologiques des Races*.

Suspected Poisoning with a Mineral Acid.

In a paper by MM. Orfila and Baruel, we have a full account of the methods adopted by these able chemists to examine some fluids in phials and in a human stomach, submitted to them by the Procureur du Roi: and although the

conclusions arrived at are only *dubitatives*, the patience and skill with which the examination was conducted are highly admirable. There had been a previous examination instituted by two parties, one of which was for and the other against the fact, that poisoning with sulphuric acid had been effected. MM. Orfila and Barruel point out the inconsistencies of both sides, and shew that the conclusions of either party were ill-grounded and immature. They, however, intimate that enough had been ascertained in the several investigations to warrant further proceedings on the part of the authorities; and they recommend that the moral evidence should be further sifted, and that probably by such a course the question of poisoning could be satisfactorily settled.

The papers of M. Huzard, on the sale of the flesh of diseased cattle, and of M. Parent Duchatelet, on the inconveniences of a carpet-beating establishment in a populous neighbourhood, were given in our pages last week, in a condensed form. There are also some other valuable articles in the No.—such as M. Lombard on the Influence of the Seasons on Mortality at different Ages, and MM. D'Arcet, Huzard, &c. on certain new Processes for Desiccating Dead Horses and Disinfecting Fæcal Matter; of which we shall probably take another opportunity of giving our readers an account.

The Cyclopædia of Practical Medicine.

Edited by Drs. FORBES, TWEEDIE, and CONOLLY. Part XVII.

WHILE our continental neighbours are so justly proud of the several *Dictionnaires* of Medicine and Surgery which they have produced and are producing, it is not without some feeling of solicitude that we note the progress of the two works of home production which are intended to supply the deficiency that has hitherto existed in our medical literature,—that of satisfactory and compendious books of reference for the use of professional men engaged in active practice. This want has been long felt, and attempted to be supplied by the importation of foreign succedanea: but besides the great expense of works brought from the continent, and the more or less imperfect acquaintance

with the doctrines, and even frequently with the language, of French and German authorities, it was not always easy to amalgamate native with foreign experience, and much valuable information was lost—in the first place by the deference which was generally, perhaps without any sufficiently good reason, paid to continental writers, and then by the perplexity and confusion into which practitioners were often thrown by endeavouring to reconcile what their leisure and opportunities ill enabled them to improve. But now that the British practitioner is about to be furnished with articles of native produce, we may augur the most favourable results from the impulse which no doubt will be communicated by the familiar use of manuals in which confidence may be reposed.

Of the *Dictionary* of Dr. Copland we had occasion to speak in high terms of praise on the appearance of the first part, and we need now only say that we strongly participate in the desire, so generally felt, that the publication of the remainder may not be much longer delayed. The *Cyclopædia* has meantime gone on steadily, and with an increasing reputation: it now draws near its completion; and if we have not given continued notices of its several monthly issues, it has been partly owing to the jealousy with which we watched the progress of an undertaking which was to confer evil report or good report on our medical literature; and partly because we were half resolved to await the appearance of the work in its completed form, in order to take a general view of its structure, proportions, materials, and workmanship. Without, however, interfering with such a purpose, we may now just apprise each of our readers as do not see the *Cyclopædia* regularly, that the present Part maintains the high character earned by the preceding ones. It contains the articles from *Plethora* to *Pregnancy* inclusive. Dr. Barlow has written learnedly and ably on PLETHORA: his division of his subject is perspicuous; and we may add that his remarks on *Bloodletting* have appeared to us to be extremely judicious and practically useful. We particularly refer to that portion of his paper in which he cautions practitioners against bleeding to syncope and convulsion, inasmuch as even the most urgent symptoms, that seem to require large depletion, may be remedied without pushing the use of the lancet to

the extent which some are accustomed to do.

PNEUMONIA, by Dr. Williams, is an elaborate article: we extract a short case, which he relates in noticing the terminations of *gangrene of the lungs*:—"An interesting case of this kind recently fell under the observation of the writer, in conjunction with Dr. Chambers and Mr. Jay, and was watched with great interest during a doubtful period of several days: inflammation in the second state affected the right lung, and signs of excavation (concluded to be gangrenous, from the odour of the expectoration) were heard at the inferior angle of the scapula: the case was greatly aggravated by the sudden supervention of a pleurisy on the left side, excited probably by the irritation of gangrenous matter in the circulation. This new attack, and the depletions necessary to subdue it, greatly increased the danger: but the powers of life ultimately prevailed; the expectoration became less fetid, more purulent, and abundant, and after some time gradually ceased under the influence of a mineral acid: the cavity progressively diminishing, was at length cicatrized, and the patient in three weeks from his worst state was quite convalescent."

The article on the SIGNS of PREGNANCY, by Dr. Montgomery, is full of curious matter, and illustrated with both erudition and the fruits of practical experience: as it is not, however, finished in this part, we may perhaps have an opportunity of noticing it more particularly another time.

MEDICAL GAZETTE.

Saturday, August 31, 1833.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

ATTENTION OF PARLIAMENT TO MEDICAL POLITY

SINCE we last addressed our readers, the first session of the first reformed parlia-

ment has been brought to a close. A memorable session it has been, but in no respect more so than in the proofs which it has given that the welfare of our profession is a matter in which the legislature now takes a deep interest. Let us consider for a moment what it has done in regard to medical matters.

In the first place a select committee was appointed to inquire into the constitution and management of the National Vaccine Establishment. This investigation was pursued with a great degree of minuteness and diligence, and we trust it will ultimately prove of service to the public; although we must say that something very like personal feeling was occasionally displayed, while the pecuniary saving contemplated cannot be regarded as very important.

In the second place a bill was brought in, under the auspices of government, for altering and amending the well-known Apothecaries' Act of 1815; and although there had been a good deal of underhand work and earwigging of official persons, and though the select committee to whom it was referred advised its abandonment for the present session, yet enough transpired to shew that the Act in question would undergo revision at an early period. We have heard that at the Home Office it was remarked that no bill was ever brought in which excited more general interest than this. Scotch, English, and Irish members, were all stimulated by their respective constituents to bestir themselves either to promote, defer, or modify it. Petitions were sent in from almost every town in the kingdom, praying for inquiry, or redress of grievances;—in almost every instance discussion ensued, and our representatives became familiarized with the wants and wishes of the medical profession throughout the different portions of the empire. Lastly, a motion was made for an address to the Crown, to grant a charter to the Univer-

sity of London (so called), with the privilege of conferring degrees in physie. The motion was withdrawn; but here again evidence was afforded that the government are prepared to innovate; and although they will not grant a monopoly for the benefit of the shareholders in Gower-street School, yet the principle of some central body in London having such a power seems to be felt, and will probably be acted upon.

The session has closed, and a temporary calm will succeed; but it is only the retiring of the wave which, when parliament next meets, will burst upon us with renewed force. Most sincerely do we trust that these "signs of the times" will not be lost upon our old medical corporations. They must surely see that the days are gone by when they can repose in the security of an old charter, or place their own dignity in opposition to the general voice of the profession. We think that the events of the last session of parliament may teach a lesson to them all. The University of Edinburgh cannot expect to enjoy its monopoly of granting degrees in physie. The Council of the College of Surgeons of London must be prepared to abandon its system of self-election. The Society of Apothecaries must make up their minds to see their sister corporations participate in the control which they now almost exclusively possess over medical education throughout this country. The Irish Colleges must equally prepare themselves for the coming storm; indeed we know that, but for the expected general inquiry, some of the gross and most impudent clauses in the Infirmarys' Bill which has lately passed would not have been sanctioned.

But it is to the College of Physicians of London that we wish now more especially to offer a few words of advice.

The Licentiates have presented a petition to parliament, which has excited much attention. Couched in strong but

respectful language, it claims interference on the part of the legislature, as a matter of justice to themselves, and of benefit to the public. Any Committee of inquiry which the parliament of next session may appoint to examine into the state of the medical profession must of necessity take an early cognizance of this petition. It complains of abuses at the very fountain of medical honours.

Our readers will doubtless have perceived that the Licentiates' petition embraces a double object;—first, the reform of the College, as regards its own members; and secondly, reform, as regards its relation to the profession generally. In both points of view it well deserves attention.

I. The petition urges the necessity of abandoning all those Bye-Laws which separate the Licentiates from the Fellows—of abolishing the very name of Licentiate—and thereby of reverting to the letter and spirit of the original charter. It is passing strange thus to see the reign of Henry VIII. displaying more liberality than that of William IV. and an eager desire manifested to return to the provisions of that early era. We should like to know on what public ground the College defend their obnoxious Bye-Laws. Do they mean to say that the licentiates are *alieni homines*—*permissi* in the strict sense of the term, not constituting any integral portion of the College, but merely permitted to practise within seven miles of London, as a mark of special favour? or is it meant to say that the Licentiates are, by their education, or otherwise, unfitted for the duties that ordinarily attach to the governing body of the College; that they are excluded from power because they are unfitted to exercise it, and that men privileged to aspire to, and in many instances actually in charge of public hospitals, and consulted about the health of the sovereign and his household, are yet incompetent to meet the other members in Pall Mall,

and regulate the interior proceedings of the College?

If the Fellows rely upon the former of these as the ground of their defence against the allegations of the Licentiates, we think parliament will soon set that matter to rights; if on the latter, the voice of the public will probably be quite sufficient to effect all that the Licentiates ask, so far as they are individually concerned.

But, secondly, the Licentiates allege in their petition, that the College, as now constituted, (even supposing the Licentiates admitted to equal privileges with the Fellows) is still unfitted for the due regulation of its branch of the medical profession, under the present circumstances of this country. They see, with all the rest of the world, the Apothecaries' Company loaded by the Legislature with high and honourable duties, and the College of Physicians left utterly powerless. They see how materially it would conduce to the general interests of the Profession throughout England, if the present absurd restriction of the control of the College, to a district within seven miles of London, was done away with; and the jurisdiction extended to every practising physician throughout England and Wales. Why should a Scotch Graduate be privileged, without further examination or inquiry, to practise in Liverpool and not in London; at Richmond, but not at Fulham. The thing will not bear investigation—it is ridiculous.

Again, the Licentiates see how desirable it is, that the College of Physicians should possess a control over the medical education of those aspiring to practise as physicians; and they foresee too, doubtless, the absolute necessity of speedily giving to some authority in London the privilege of granting degrees in Physic: a privilege which might nowhere so well be vested as in the College of Physicians—reformed, of course, in its constitution, uniting the

interests of all the practising physicians of England, and profiting by all the talent which is attainable.

Do the President and Fellows of the College of Physicians not see these things? Can they shut their eyes to the inevitable march of events; and do they not perceive that even supposing the dignity of Oxford and Cambridge would be somewhat lowered by the closer approximation of the Graduates of Edinburgh and Glasgow, they would be amply recompensed by the additional honours and the higher privileges which a reformed College might boldly ask, and which no reformed Parliament would venture to deny them?

These are the reflections which a careful perusal of the Licentiates' petition has impressed upon our minds, and heartily glad shall we be, if, by thus putting them forth, we may succeed in convincing the College of the necessity of setting about the great work of internal reform. The Bye-Laws of which the Licentiates so loudly, and we think so justly, complain, are not the work of the present race of Fellows. They were framed in times long past, by men bred in different habits; and sure we are that the present men would never have originated measures the obvious effect and intention of which are to exalt themselves at the expense of their professional brethren. There can be no discredit, then, but there can, and there will be, much honour, in revising the labours of their predecessors, and adapting their Bye-Laws to the circumstances of the times, to the wants of the profession and to the changes of the country. Fervently do we trust that the internal reform of the College will be effected by the liberality and good sense of the Fellows themselves, and that the Licentiates may not have to knock again at the door of parliament to obtain the justice which ought to be freely granted them by their brethren of the profession.

STATE OF CHOLERA IN THE METROPOLIS.

ACCORDING to the information which we have been able to collect from authentic sources, the number of cases of cholera during the week just concluded is rather less than occurred during that which preceded it, showing the disease to be slowly on the decline; and this view is further corroborated by the returns in the Bills of Mortality, the number of deaths having dropped down from 186, the week before last, to 125 in the last week. Various circumstances have concurred to give rise to a general opinion that cholera is and has been more prevalent than we believe to be the fact. It is undeniable that to judge from the number of patients affected with the disease, who have been attended by private practitioners, we should be warranted in declaring the malady to have been considerably more rife than last season; but it is to be kept in mind that this depends in a great measure upon the discontinuance of the cholera hospitals, in which many of the poorer classes were provided for on its first irruption; and also, it must be added, upon its visitations having been more frequently extended to those ranks of life in which the assistance of the medical practitioner is immediately had recourse to.

ST. GEORGE'S HOSPITAL.

CLINICAL REMARKS ON

Necrosis of the Femur—Haemorrhage—Erysipelas—Abscess in the Knee-joint—Amputation.

By MR. CÆSAR HAWKINS.

THE subject of necrosis is at all times a very curious and interesting one; but when the femur is the situation of it, this disease becomes exceedingly important and dangerous, and presents some points of surgical interest in which it differs from the same disease in other bones; and as I have two cases of necrosis of the femur at present under my care, I will make them the medium of placing a few observations upon the subject before you. The history of these cases at the time of their admission is as follows:—

1. Frederick Willis, æt. 13, admitted December 19, 1832. One month before his admission he fell down and struck his left knee, which was followed by a good deal of pain, with general swelling of the whole thigh, and some also of the leg and foot; the pain becoming at last exceed-

ingly severe, and being accompanied with much fever. The swelling, at the time of admission, was confined to the lower half or two-thirds of the femur, and matter was felt under the vasti muscles, with much tenderness over the abscess, and a good deal of febrile excitement, but without any redness or discoloration of the skin covering it.

2. Jeremiah Chandler, æt. 24, admitted November 21, 1832. Three years and a half ago he felt acute pain in the knee, which came on suddenly while he was at work; which was followed immediately by much swelling and fever. He was confined to bed three months, and was not able to return to work for two years. The thigh was poulticed, and had emetic tartar ointment applied at first; but an abscess formed, which in two months burst on the inside, and continued to discharge till the time of his admission, when there was an opening leading down to dead bone, which was surrounded by new bone. He did not suffer locally from the disease when admitted, and his health was good.

The history of these two cases, then, is that of acute inflammation of the bone and periosteum, ending in necrosis of the femur; and two different periods of the disease are presented to your notice. In one case, you will observe that the disease arose from an injury to the knee, and in the other it took place spontaneously; but in whatever way the inflammation occurs, whether from a blow or from cold, or without any evident cause, its course is nearly the same, in the same kind of inflammation.

But, in reality, acute inflammation of the periosteum of the long bones occurs in two very different forms: in the first of these the inflammation is of a healthy character; it is accompanied with more or less inflammatory fever, with a good deal of local pain, commencing for the most part about the knee-joint, and the abscess which forms consists of healthy pus, surrounding the bone, the periosteum of which is separated from it along with the muscles which are attached to it. This kind of inflammation you saw in an early stage in Willis; and was, I have no doubt, the character of the inflammation in Chandler also. It commonly terminates favourably, and new bone is readily formed, because the periosteum is not destroyed.

In the other kind of inflammation, on the contrary, the abscess is of a different character; the pus is in smaller quantity, and is mixed with shreds of dead periosteum and cellular membrane and muscle. It is a sloughy abscess, and is of an exceedingly dangerous nature; and if the patient does survive the first period, the periosteum having in great measure sloughed away, new bone is not formed to supply the place of that which dies, and the patient will

sink under the irritation excited by constant discharge, unless the limb be removed by amputation. The fever which accompanies this form of inflammation is typhoid, instead of being inflammatory, as in the other; and the local pain is frequently not at all in proportion to the constitutional disturbance. In a case of this kind which I was called upon to see, the father of the patient, who was a medical man, had wholly mistaken the nature of the case, and had bled him repeatedly and largely, as for inflammation of the chest, although the fever depended upon this kind of foul abscess over the tibia. When I was called in, I laid the abscess open, which exposed nearly the whole of the tibia completely dead; but the lad was then sinking with typhus fever. Another patient who was under my care, used, in the delirium of typhus fever, to get up repeatedly and walk about the ward of the hospital, if he was not watched,—so little pain did he suffer from the disease, although a foul sloughy abscess was forming around the whole femur, which I opened by incision through one of the vasti muscles and between the flexor muscles in the ham, by the side of the popliteal nerve. Mr. Keate mentioned to me a case in which the cause of a typhus fever was pointed out to his notice by his judiciously attending to his patient's crying out, in his delirium, "Holloa! what are you pulling my leg for?"—the pain of the inflammation raising this idea in his mind.

The inflammation not having been subdued in the first instance, for which purpose leeches, fomentations, and the mercurial action of calomel with opium, are most efficacious (if the degree of inflammatory fever allows of mercury), abscess is formed; which was the state in which you saw Willis on his first admission into the hospital. I think it better in general, in the healthy kind of abscess, not to open it early, but to let it become fully formed, while the fever changes its character from an inflammatory one into a stage of irritation. If, indeed, the patient suffers much from the rapid formation of matter, while the swelling is tense and acutely sensible, you must open the abscess while it is still inflamed, in order to relieve the patient and prevent the forcible separation of the periosteum from the bone to a greater extent than would otherwise take place. In Willis, however, I delayed the opening; and the consequence of this was, that the quantity of matter was much lessened, and he suffered much less both locally and constitutionally. This amendment was assisted by perfect quiet, with fomentation and poultice, and by a calomel and jalap purgative, on the 20th December and 1st of January. The constitutional change which I wished for had

also taken place, so that he required a somewhat better diet, and slept and eat much better. In the sloughy abscess, on the other hand, you cannot make an incision too early, even when the quantity of pus is very inconsiderable.

January 6th, however, Willis began to complain of more pain; the swelling began again to increase, and on the 8th I made an opening into the abscess and let out a large quantity of pus. This was followed (as it often is) by an increase of fever; for which he took saline mixture and antimony, but which would probably have been much greater if I had opened it in the first instance. This soon subsided, and on the 17th he began to take some bark and sulphuric acid, and had some porter allowed him.

Now comes the very important question in abscess around the femur—whereabouts is the opening to be made, and what is to be done while the abscess is discharging? You will say, perhaps, open the abscess in the most depending position, and make counter-openings if the abscess has burst in an unfavourable situation. In cases of abscess of the thigh, with necrosis, you will, however, find yourselves frequently baffled in this object. The position in which the patient almost always lies is with the knee bent on a pillow, the hip bent forwards, and the thigh partly turned outwards. The place in which the matter points, and the abscess bursts, if it is left to itself, is just above the knee-joint, below the lowest fibres of the vasti muscles; and generally it is on the inside, where the vastus internus turns round to be inserted above the patella. This is, therefore, in the patient's usual position, the very highest part of the abscess, and the matter is necessarily never emptied, and unless it discharges freely will force its way upwards towards the trochanter; being prevented every where else from coming to the surface by the thick vasti muscles meeting behind at the linea aspera, and in front beneath the rectus. The most depending position will be on the outside of the thigh, at the part of the abscess nearest to the hip; but very often you can scarcely tell exactly how high the abscess reaches. If you open it there, you have a deep and large incision to make through the vastus externus, and after you have made it, you find, in a short time, that the action of the muscle alters the relative position of the deeper part of the opening with regard to the more superficial, or the muscle granulates so quickly that the orifice soon becomes closed. This is especially the case if a counter opening is made in this situation while one already exists near the knee; and you thus find yourself again obliged to make use of the opening which

nature has chosen, however unfavourable it may appear. In Willis, however, the *vastus externus* being thin, I did succeed in keeping the opening permanently discharging, by once or twice slightly enlarging it when it was threatening to become obstructed. In a stout muscular person, however, so much difficulty is experienced from the cause I have mentioned, that it is generally better to keep the orifice near the knee sufficiently large to prevent bagging of matter, while compression is made by straps of plaister round the upper part of the thigh (in the uninfamed state of the abscess), so as to prevent the matter from making its way towards the hip. Provided the quantity of matter is not very great, this is better than irritating the patient by repeated attempts to get another opening through the *vastus externus*; by which also, blood, getting into the abscess, will sometimes excite fresh mischief.

But I have another circumstance to point out to you with regard to abscesses connected with the femur, which you may easily believe from what you have seen of Chandler's case, and which renders it the more desirable to procure, if possible, an opening on the outside rather than on the inside of the thigh;—it is the frequent occurrence of alarming and even fatal hæmorrhage from the incision which you make in order to enlarge an opening situated at the margin of the *vastus internus*. This incision, I conclude, opens the anastomosing branch of the femoral artery, as it crosses towards the front of the knee. I once had very alarming bleeding at the time I made an opening in this situation, and had considerable difficulty in finding the vessel; for which purpose I was obliged to make the incision still larger. More frequently, the vessel is opened by slight ulceration of the edges of the wound some days afterwards; the consequence, no doubt, of the excited and irritable condition of the circulation during this tedious complaint; and of this hæmorrhage I recollect two patients dying. One was a patient in whom an abscess formed under the *vasti*, of the same kind as in necrosis, after an ivory tumor had been removed from the femur; the other was a case of necrosis of this bone. There was a third patient, under Mr. Babington's care, about two years ago, who was very near dying after repeated returns of bleeding, apparently from the same vessel; which, however, was finally stopped, when he was almost exhausted, by tying the superficial femoral artery. So that you must by no means consider the danger from this cause, in necrosis of the femur, as merely imaginary.

Now let us follow Willis's case a little further. The abscess having been opened

on the 8th of January, and the opening once or twice slightly enlarged, the boy continued gradually to improve in health till the middle of April: his health having been supported at times by bark and quinine, as well as by porter and good diet, had become very good; and the thigh was so much improved, and the discharge so much lessened, that he was allowed to sit up daily, the limb being supported by strapping and by a splint, lest, during the separation of the dead piece of the femur, which was several inches long, the new bone which was forming should be broken—an accident which I have seen, and which is exceedingly difficult to treat: indeed, when it does occur in the thigh, the limb will generally require to be amputated, as the insufficiency of the new bone to support the weight of the limb commonly shews such a state of system that the patient is not likely to get well unless it is performed.

About the 20th of April, however, an unfortunate attack of erysipelas completely changed the state of things: it was of a somewhat severe character, and of the low kind that we most commonly see in the hospitals; and the effect of it has been the formation of one or two foul abscesses in the leg, and (a circumstance of more importance) an abscess in the knee-joint, with ulceration of the cartilages. Now you will observe that the thigh-bone being in a state of disease, this limb was the part which was attacked, although every thing was at the time going on favourably; and the case shews you how formidable an attack of erysipelas is upon the whole limb, affecting every texture, though we usually regard it as a disease only of the skin and subcutaneous textures. A man was once under my care with inflamed synovial membrane of the knee-joint, and an attack of erysipelas caused the same rapid ulceration of the cartilages of the knee, with very extensive abscesses; of which he died after several weeks' suffering, without any opportunity of my removing the limb. A poor chimneysweep was under my care, with necrosis of the femur and extensive abscess, as in Willis. This went on very well, however, and a large tumor of new bone was felt around the ends of the dead piece—one near the knee-joint, the other about half-way up the thigh. An attack of erysipelas came on, and caused the entire absorption of the new bone, with considerable increase in the extent of the dead portion of the bone; so that the next time the prominences formed by the new bone at the ends of the dead piece were distinguishable, the upper was nearly as high as the trochanters, and the lower one was very near the knee-joint. In the misshapen bone which I now shew you, you may see the consequence of an attack of erysipelas upon a fractured thigh-bone.

The patient had recovered from the accident, and was in a few days going to be allowed to walk about, when a severe attack of this disease took place in the foot and leg. Besides the most extensive abscesses in the leg and thigh, a large mass of new bone in the seat of the fracture was absorbed; the bone became again flexible, and in consequence of the great irritation of the abscesses, with much sloughing of skin and cellular membrane, during several weeks that the patient lived, and the total impossibility of employing pressure in any part of the limb, union took place a second time in this distorted position. The bone united too, although one of the abscesses was situated below the vasti, and communicated with the fractured bone, a portion of which you will see dead, and enclosed in new bone. So that the whole case formed, as it were, a very curious instance of necrosis.

Thus, then, the joint in Willis's knee is completely disorganized, and I conclude I shall have to amputate the limb, as soon as his health becomes sufficiently restored, as the only means of saving his life;—not, indeed, merely on account of the abscess in the knee-joint, for of that alone there would be a possibility of his recovering. A young woman, for instance, called at my house, a day or two since, with a very useful limb, although I was obliged several years ago to make two openings into her knee-joint. But I expect that I shall have to amputate this limb because of the extensive mischief in the thigh, in addition to the abscess in the joint.

[The operation was subsequently performed, as Mr. Hawkins anticipated, and formed the subject of another Clinical Lecture, which we may perhaps give.]

Now here, again, is another practical question with regard to Willis's case. You saw that I opened the abscesses formed by the erysipelas in the leg as soon as they were perceived, while I did not do so with the knee joint, notwithstanding the excessive pain which he suffered while the abscess was forming; because, in fact, I believe it to be good practice not to open an abscess in a joint very early. You must distinguish between the pain which arises from the ulceration of the cartilages during the formation of the abscess—and which, you know, is often very great for several weeks, before matter forms—from the pain arising from the abscess itself in the joint; and if you are not obliged to open it from distention, it is better to wait till the ulceration has proceeded further; you do not prevent this process by doing so, and you avoid the irritation which will sometimes follow your puncture of the joint in an earlier stage: by postponing it, in fact, you gain the relief afforded by opening an ab-

cess, instead of the risk arising from a punctured wound of a joint.

The next fact you will observe is the contrast between the effects of a disease of the skin, as erysipelas may be called, upon the knee-joint, and those of a deep abscess very near the joint, with acute inflammation of the femur, forming, as it does, part of the joint itself. The fact is, you will find in practice that the effects of necrosis of the thigh bone, or indeed of any other of the long bones, very seldom extends into the nearest joints, but fortunately for the patients is almost always bounded by the epiphyses, and confined, therefore, to the central shafts. In the little chimneysweep, whose case I have already alluded to, the knee joint was swelled very considerably with synovia at the time of his admission, and the ligaments were so relaxed that very considerable lateral motion of the leg upon the thigh was allowed, and yet in spite of the mischief of the erysipelas, the joint returned to its natural condition, and when I saw him some time afterwards the dead bone had nearly come away, and he was walking about. In a boy whom you may have seen attending the hospital as an out-patient, the whole shaft of the tibia died, and was removed by operation, leaving the limb for a long time flexible, as if with fracture: both the ankle and knee joint were much swelled on his first coming under my care, and there was some bone exfoliating even from the epiphysis itself, close to the knee joint, so that I considered the loss of the limb as almost inevitable; yet no ulceration of the cartilages took place, and he has a very useful leg. Still, however, it does occasionally take place, and more frequently in the necrosis which happens in adults from cold or injury, than in young persons, the epiphysis in whom is still separated from the shaft by cartilage; and when this ulceration does take place, with abscess in the joint, you can scarcely expect to save the limb.—[Mr. Hawkins then showed a preparation in which the cartilages had been thus destroyed by rheumatic inflammation and abscess of the femur, but the patient's health gave him no opportunity for amputation.]

A patient having survived the irritation of an abscess during the worst stage of its formation, the very curious process of reproduction of the dead bone is next seen—a wonderful operation of nature, which I am never tired of watching. You saw this in its early stage in Willis, till it was unfortunately put an end to by the erysipelas, and you have seen its result, although three or four years had elapsed, in Chandler's case.

In Willis, the periosteum, having been

thickened by inflammation, was separated from the surface of the shaft, remaining still attached to the lining surface above and below the dead portion; matter is secreted within it, and thus the periosteum, united to the part around, forms the parietes of an abscess in which the dead bone lies; but at the same time, if the matter is secreted rapidly, the periosteum does not remain in one entire piece, but more extensive abscesses are formed, frequently filling the whole of the cavity formed by the vasti; so that while these abscesses communicate with that in which the dead bone lies, there is still some thickened periosteum covering the living bone elsewhere, the pus being in this manner on the inside of the periosteum at one part, and on the outside of it at another. Supposing, therefore, that matter is felt nearly all the way up to the trochanters, it does not follow that the whole of the thigh bone, which is enclosed in the matter, is dead, but the periosteum may be vascular enough to preserve part of the bone, although separated by a good deal of matter from the surrounding muscle. In Willis, it was evident by the probe that the entire circle of the shaft was dead at one part, and the dead bone in front could be felt for several inches in an extensive abscess. Still you observed that new bone began to form, which in some measure surrounded this old bone. If the periosteum is much destroyed, as in the foul abscesses I before described, new bone cannot be formed in sufficient quantity to preserve the limb; but in Willis, the abscess having been of a healthy kind, this curious process went on favourably. At first, it is generally formed at the two extremities of the dead piece, and two prominent ridges mark the boundaries of the living and dead portions; then, as the matter begins to diminish in quantity, the periosteum returns nearer to the dead shaft, condensed and united to the parts around; then this begins to secrete new bone, and a case is formed entirely surrounding the dead piece, with the exception of one or more openings through which matter continues to pass away. At this period the dead piece is still attached to the living portion of the shaft, but next ulceration takes place at the extremities of the mortified bone, and the dead portion or sequestrum separates into the cavity of the new bone. In general, before this takes place, the new bone is firm enough to bear the weight of the limb, being attached to the epiphyses, or wherever else the mortified piece terminates; still sometimes the separation may go on more quickly; so that you will see the propriety of supporting the limb by strapping and by pasteboard, or other light splints, as I di-

rected in this boy. So far, then, you observed this process in Willis, and you saw how little pain or inconvenience was felt while it was going on, so that he sat up and moved about freely on crutches. Dr. Macartney published a case in which nearly the entire shaft of the femur separated in one piece, and stuck out of the surrounding bony case, while the patient was going about, the end getting in the way of his breeches, till one morning in bed he gave it a tolerably firm pull, and extracted it.

In this state you will often see nearly the whole length of the tibia or humerus extracted by operation in this hospital.

More frequently, if it is left to itself, (the removal of the greater part of the femur being too severe an operation to be performed as early as you may do it in the other bones,) the dead bone is divided into several pieces, and comes away through numerous openings, during a considerable time. I may allude again to my little chimneysweep, in whom almost the whole shaft thus came away, in about a year, through ten or fifteen openings, without any assistance from surgery; for he did not choose to shew himself, lest any operation should be performed, till the exfoliation was nearly completed. It is surprising how much the dead piece is thus broken up and diminished by absorption, during its contact with the living parts, so that the pieces which actually come away are often not a quarter of the bulk of that which has died. This power of absorption is shewn by an experiment of Sir W. Blizard, who put a piece of dead bone on a common ulcer of the leg, and found it much diminished in size.

Sometimes, a considerable portion remains locked up for a long time, and then becomes accidentally loosened, or produces fresh irritation, and successive abscesses are formed, to allow of the separate portions coming away, or an operation is required for their removal, as in Chandler. When at last the whole has come away, it is astonishing to see how nearly the limb is restored to its original state, the great misshapen case of new bone being gradually absorbed again on the outside, while more is deposited on the inside of the case, till at last you can scarcely see any difference between the diseased bone and the sound, in shape and appearance.

Mr. Hawkins shewed several preparations illustrating the separation of the sequestra, and then proceeded to describe the operation in Chandler's case, which we must reserve till the next number of the Gazette.

HOSPITAL OF ST. LOUIS.

Hydatids of the Liver—Puncture followed by Incision: Evacuation of a large quantity of Acephalocysts—Cure.*

THE following case has occurred to M. Biett:—A young man, scarcely 18 years of age, of lymphatic temperament, was admitted at the St. Louis on the 29th of last April. He resided in a village in the department of the Maine, where he exercised the trade of a sawyer. About three years ago he became sensible of the existence of a tumor in the abdomen, which was constantly indolent, and which gradually increased without his experiencing any derangement of the digestive functions. However, he got thinner and lost strength: and seeing himself abandoned by the practitioners where he was, he resolved to see what could be done for him in the capital. When admitted into the St. Louis, the fatigue of his journey had aggravated his state. A tumor of considerable size occupied the right hypochondrium as well as the epigastrium, extending partially to the left hypochondrium, and downwards to the level of the umbilicus. Above, it was lost beneath the ribs. The tumor was rather smooth, without strongly-marked furrows: firm pressure produced but very moderate uneasiness. The patient was every instant threatened with suffocation; his countenance was mottled—yellow and blue, and expressive of extreme anxiety; his pulse was small, concentrated, frequent; and he had daily vomiting greenish matters. M. Biett, struck with the alteration which the countenance had undergone, and having made up his mind as to the nature of the case, informed M. Jobert that he had a surgical case in his ward. After an attentive examination of the tumor, this gentleman agreed with M. Biett as to the propriety of an *exploratory puncture*. A spot was selected on the convex surface of the liver towards the left lobe, which presented manifest fluctuation. A trochar was plunged in, when there issued in a jet a considerable quantity of serous fluid. The patient seemed to be relieved for some days after, but the puncture having healed, the symptoms recurred.

April the 29th.—M. Jobert, calculating upon the existence of adhesions, determined on making an incision on the summit of the tumor. This aperture was made, in conjunction with M. Biett, at four fingers' breadth beneath the margin of the false ribs, and at two fingers' breadth from the linea alba of the right side. The liver was cut through to the depth of from an inch to an inch and a half, and appeared healthy in its structure; but a serous fluid

was elicited by pressure, and the bistoury once more introduced, penetrated a cyst with thick walls, and which presented a cavity of some inches in diameter. In a quantity of serous fluid, a considerable number of separate hydatids were seen to float. Some of these were very large, and could only pass out by elongating themselves, after which they immediately regained their globular form. Injections were made into the cyst of alcohol and water, and a female sound left in it. During the two months which have since elapsed, some hydatids and serous fluid have been evacuated almost every day; the abdomen is soft, with little pain: the patient is rather weak, but he takes some food, and has little fever.

FÆTAL CYCLOPS.

M. LACROIX read a memoir lately before the French Academy of Medicine, in which he gave an account of a case of cyclopism, occurring in a female fœtus. From the anatomical details, it appears that this is the only case of the kind in which an ethmoid bone has been found; and the second case in which the eye has been found destitute of an optic nerve. The latter fact is important, inasmuch as Tiedemann, in his memoir on Cyclopism, has doubted the possibility of its occurrence, and refused his credence to the solitary case quoted by Magendie, because it was solitary.—*Journal Hebdomadaire*.

GRÄFE OF BERLIN.

THIS distinguished surgeon is at present in London, and was presented to the King, on Wednesday last, at the *entrée levee*.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE URINARY
ORGANS.

—
EXCESS OF UREA IN THE URINE.

THERE is an affection very similar to diabetes, and which is sometimes mistaken for it, and that is, where the urea is in excess. I do not know that the disease has been noticed by any one except Dr. Prout, but I have seen several cases of it, all of which have done well.

Symptoms.—There is debility; lowness of spirits; pain in the loins; thirst; an excessive quantity of urine; a loss and diminution frequently of sexual power; frequently irritation at the neck of the bladder; a frequent desire of making water. The urine is pale, and likewise heavy; perhaps the specific gravity is from 1.025 to 1.030; but it is acid, and soon grows alkaline. On evaporating the urine, you find there is no sweet extract; and if you add strong nitric acid to the fluid, you have a precipitation of the urea.

This state of the urine is frequently seen where the phosphates are in excess. Equal quantities of nitric and muriatic acid must be added, in order to produce crystals.

Treatment.—The remedy for this state, as in diabetes, is opium, and likewise iron. I have seen these cases yield to the exhibition of one, or both these remedies. Dr. Prout has cured many cases which were thought to be diabetes, till he examined the urine and found no sugar in it. The

patient complains of the symptoms I have just narrated; and if you find it to be this disease, it may yield to the remedies I have named. If the patient's health be improved, the disease may cease spontaneously. It is by no means a formidable disease, like the formation of sugar.

Fluids liable to the same morbid changes as the solids.—You will recollect I mentioned, before entering on the consideration of particular parts, that just as with respect to the solids we have an excess of development, an alteration of natural structure, so the same is observed occasionally in the fluids; the natural constituents become changed in their proportions; that just as in one part of the body we have cartilage, or bone, where it ought not to exist, so in regard to the fluids, we find them containing something which ought not to be there, but still something natural to the body, or containing something in excess. Again, as in regard to structure we sometimes have a new structure altogether, a structure that ought not to be in the body at all, such as melanosis, if you choose to call it structure, and scrofulous disease, which is a foreign substance, so occasionally in the fluids we find things that ought not to be there at all, of which sugar in the urine is an instance. We have changes in the fluids analogous to transformations, and we have further changes which are analogous to new formations in the solids.

Before speaking of that disease in which there is sugar in the urine, which is a new formation altogether, and not found in any part of the body, I ought, for the sake of uniformity and consistency of plan, to have said a word or two upon some other affections, those in which there is merely a transformation, if I may so say—in which things exist in the urine which are found naturally in the body, although they ought not to be present in the urine.

SEROUS URINE.—One of these articles is serum, the presence of which is easily

ascertained by the application of heat. It coagulates, as you know albumen does, at 150 degrees, or it will coagulate by adding to it a small portion of acetic acid, and then prussiate of potass. I spoke of this as sometimes occurring in inflammatory dropsy, sometimes where there is no inflammation to be discovered, and sometimes where there is no disease of the kidney to be ascertained. When serum exists in the urine, the urine may be of its natural quantity, or it may be below it, or it may be in excess. Generally the urine when made is pale; sometimes it is, when first made, a little opaque. I need not say any thing more about this, as I spoke of it so fully when treating of dropsy.

CHYLOUS URINE.—Fibrin sometimes exists in the urine, not as a deposit from the ureters or bladder, but really as the product of the kidneys; at least it was so in a case which I saw. I have seen only one case, but that I repeatedly examined, and I found it was the fibrin of chyle. There is the fibrin of chyle as well as the fibrin of blood; and as it is sometimes found in the urine, we may say that it exists in the urine. The case that I saw was very remarkable. The woman was otherwise in very good health; but soon after she made urine a coagulation took place, and there was a quantity of something exactly like *blanc mange*, as much as a tea-cup full. Occasionally it coagulated so that she could not make water. I never saw such a case before; but I shewed the discharge to Dr. Prout, who examined it, and ascertained that it was chyle. She went on in this state for two or three years; and in the midst of it all she gave birth to a child; it seemed to make no difference in that way. I have every reason to believe she is now alive. Dr. Prout has seen six or seven cases since that time. I wished to make some observations upon her, and begged her not to take any food for twenty-four hours, in order that I might see if it would check the formation. There was this change produced, the coagulum approached nearer to blood; it had a fine pink colour; and the more she fasted the more it approached to red—it was more and more converted into blood. There was no fresh food taken to form fresh chyle, and consequently the chyle became more like blood. There was a fluid around this which was very serous, contained a good deal of albumen in solution, and, of course, there was urine; but the fluid scarcely smelt of urine till it was concentrated. One hundred grains, on evaporation, gave only half a grain of urea.

Nothing was done in this case; but Dr. Prout told me, that by giving opium continually two or three times a day, he had been successful in curing this disease. The quantity of substance was altogether de-

ceptive to the eye; for on evaporating this large coagulum and examining it, there was very little solid matter, and therefore the loss to the system was by no means so great as at first sight we must have imagined.

DISCHARGE OF FAT.—Occasionally fat has been found in the urine. I stated when speaking of a discharge of fat from the intestines, that in some cases mentioned by authors fat was found in the urine; and in one case, in a lady whom I know, but whom I do not attend, the gentleman under whose care she is assures me, that a large quantity of fat is discharged together with the urine.

URINARY SEDIMENTS.

In regard to concretions, they are of a mixed nature; they may consist merely of the natural constituents of the urine, and therefore be analogous to those diseases of the solids called *transformations*, in which things naturally found in the body are present; or they may be new substances, such as ought not to exist in the body at all, being analogous to those which are termed *new formations*, or non-analogous changes of structure.

I now, therefore, shall speak of those substances which are termed *urinary concretions*; before, however, entering on them, it is necessary to make some general remarks on the nature of urine and its constituents.

Healthy urine, when it is first made, is acid; it will stain litmus paper; and if the bladder be not very retentive, if persons be not very particular, as is sometimes the case with old gentlemen, their breeches will be stained; you observe they are red from the acid in the urine. Chemists in general say that the urine is acid when it is first made; but Dr. Prout contends that it is not pure uric acid, but lithate of ammonia, that stains litmus paper red.

Causes of pink and red sediment.—But the urine sometimes contains nitric acid, and you know that if nitric acid be added to lithic acid, erythric acid is produced. It is of a very fine scarlet hue, and is a substance that does not exist naturally in the urine. If you add to this erythric acid pure ammonia, you then have another change, a purpurate of ammonia is produced; and if you treat this purpurate with potass, and then again with sulphuric acid, you have a new acid formed, called purpuric acid; so that erythric and purpuric acid do not exist naturally in the urine, but are the result of other changes. Thus you perceive that, if nitric acid be formed by disease in the urinary secretion, it may give rise to the presence of the purpures; purpuric acid may be formed;

and then, as there are soda, potash, and ammonia, in the urine, you may have the purpurates of soda, potash, and ammonia; and if these are added to the lithate of ammonia, then the lithate of ammonia which may exist in the urine becomes of a fine pink or red colour, and you have a pink or red sediment; and therefore you see that the pink and red sediments are essentially lithate of ammonia, which is formed in excess, so as to be insoluble at a common temperature; and they are deposited in the urine because they are in excess, or because the acid is in excess; they are super lithates. You know, of course, that the lithate of ammonia, and the other lithates, are white of themselves, but from the presence of the purpurates they acquire a red or pink colour; and if the yellow matter of the urine be absent, as in hectic, then instead of being red they become pink. All this however, comparatively, is unimportant.

Now in pyrexia, nitric acid appears to be formed in the urine; and the lithates, particularly the lithate of ammonia, are in excess; and in consequence of the excess of lithic acid, or of lithate of ammonia, and the formation of the purpurates by nitric acid, you have a copious sediment produced, which is red; and though it is originally owing to the nitric acid, yet it is some of the lithates, generally the lithate of ammonia, which has been rendered red by the presence of the purpurates.

Now all this may be produced by the sympathy of the kidney with any other organ that is affected. From mere catarrh, slight inflammation of the mucous membrane of the air passages, you will have this effect produced. In fever, and in inflammation, the same occurrence takes place. If there be organic disease, especially of the liver, it has a tendency to produce pink sediment—that is, it causes an absence of the yellow matter, and consequently it is pink.

Very trifling things will produce this state in some people. A little pie crust, or pastry, in some may cause a red or yellow sediment. Anxiety, strong exercise, or, as I have said, the slightest causes or derangement, will give rise to it. Hence Dr. Prout has called this “The sediment of health,” though it is seen in disease; by which he means that it occurs from such slight causes that it is hardly worth while to consider it as an indication of disease. All is not right, but still it will happen every day, and indeed by far the most frequently when the person is in a state which you cannot denominate indisposition. Generally the redder or the pinker the urine is, the more scanty is its quantity.

This sediment you are aware does not appear till the urine cools. The temperature of the urine when in the body is sufficient to keep these matters suspended, and therefore it is generally made clear, and it is not till the fluid is cool that the sediment appears; and then, if the person a short time afterwards make water, the heat of the fresh quantity of urine causes it to be dissolved again, but of course a second cooling occurs. For this reason we observe this sediment far more frequently in cold than in warm and hot weather. In hot weather, though the urine perhaps contains every thing necessary for such a deposition, yet it does not produce it; but in cold weather, if it so happen that the urine is not in excess—as it so frequently is—if we are not chilled, if we are in a warm room, if we do not diminish the perspiration, the quantity of urine remains the same as before, and then on making water in a cold room you are almost sure to have this sediment, although under the same circumstances in summer you would not, the external heat being quite sufficient to keep these ingredients in a state of solution.

Varieties in the shade of colour.—The sediment when red runs by gradual approaches through a light brown, the colour of ripe hazel nuts to absolute white. There is the greatest variety in the shade of colour; sometimes it is red, sometimes it is reddish, sometimes it is the colour of a hazel nut, and so on, fainter and fainter till the sediment is nearly white, or perhaps quite so.

Red and pink sediment shew acidity.—When you see red and pink sediment, the urine is more acid in general than in health; and when it approaches more to yellow it is less acid. It shews that there has been less nitric acid, less of the purpurates have been formed; a less change therefore has passed on the lithate of ammonia by the purpurates, and therefore you have a fainter colour. This is all very intelligible, but it is necessary to shew it, in order that it may be fully understood. In those states of the body in which there happens to be nitric acid formed in excess, you have the purpurates; and the purpurates being present, and united with lithates, you have a red or pink colour, just as it may be, and therefore you find the urine in the case of red or pink sediment, acid; but if it so happen that nitric acid is not formed in abundance, then of course the purpurates are not produced in so much abundance, and therefore they cannot change the colour of the lithates, which is naturally white, to a red or pink hue. Hence, whenever you see this sediment red and high-coloured, you generally find the urine very acid, and in proportion as it is paler, goes through a

faint brown and approaches to white; in that proportion generally is the urine less acid, and it even may be deficient in the natural quantity of acid, and be rather alkaline. The urine where there is acid is high-coloured; but when the sediments are pale, and the urine is not acid, then the urine generally is pale also.

Oxalic acid found in the urine.—Besides the nitric acid, oxalic acid has been found in the urine, and to form a sediment, but it has not been a powdery, but a crystallized one, and it is in union with the oxalate of lime. Once only has Dr. Prout seen a powdery sediment, what he calls an amorphous uncrystallized sediment of oxalate of lime, and then it was mixed with ammonia. We shall see with regard to oxalate of lime that one calculus consists entirely of it, and the tendency to produce oxalic acid, it is said, has been sometimes traced to eating sorrel, which contains that particular acid; but of that I will speak presently.

White sediments consist of the phosphates.—If you observe the sediments of the urine to be absolutely white, then they are not the lithate of ammonia, but the phosphate of lime, the phosphate of magnesia, or the phosphate of ammonia, or more than one of these. In this state of things, when there is this absolute white sediment of the phosphates the urine is not acid; on the other hand it is alkaline—it is absolutely alkaline, or it becomes so very soon after it is made. It is rare certainly for the urine to be quite alkaline. Sometimes the urine is all but alkaline, and it is no sooner made than it emits a strong smell of ammonia. The best test for alkalis is not turmeric, but litmus paper which has been exposed to acid. Reddened litmus paper is the most delicate test; the smallest quantity of alkali brings back the purple hue.

Variations in the urine.—When the sediments are white and depend upon the phosphates, the urine differs in other particulars from the urine made when the sediment depends upon the lithate of ammonia. The urine, instead of being high coloured is pale, with a faint greenish hue, and instead of being scanty, as in the case with acid urine, it is generally abundant, and very soon after it is made it undergoes such a high degree of decomposition that it becomes very offensive, and smells of ammonia. Still there is one exception to this, and that is, when lithate of soda has been deposited. I have had one case of this description, and I suppose others have had many, where there was a white sediment in the urine, but it did not depend upon the phosphates, and therefore the

quality of the urine was like that which is seen when there is red sediment. The lithate of soda, if not coloured by the purpurates, is perfectly white. It so happened, in this case, that the lithate of soda was deposited pure, but as it was not a phosphate the urine was not of that quality which occurs when the phosphates are deposited. It was not abundant, but scanty; it was not alkaline soon after it was made; but it was acid, and tinged litmus paper red.

One set of sediments consists of lithates deposited in abundance, and they are generally tinged with the purpurates; another set are always white, and they are phosphates. In one set we have acid urine, in the other alkaline; in one set the urine is scanty, in the other it is abundant—namely, where there is an alkaline phosphatic disposition; in one it is high-coloured, in the other it is pale, and frequently of a reddish hue. You may sometimes have pure lithate of ammonia, and a white deposit, just as if it were ammonia, if it so happen that the purpurates are not formed.

Phosphatic Urine dependent upon Debility.—Now this opposite state of the urine where the phosphates are deposited—where the urine is abundant and the urine is disposed to alkalescence—does not shew an inflammatory state. The other secretion of urine shews an inflammatory condition, but this, where the urine is abundant, is alkalescent and does not stain litmus paper, is connected with an irritable state of the system—a state of irritation—a state of debility.

The two conditions run into each other.—However, these very states run into each other: you will have persons making alternately one description of urine, with one kind of sediment, and then the other; and you will have persons verging from one to the other, so that there is no certainty. Persons are in a sort of mixed transition state, where matters are much confused. Most probably they begin with acid urine and the lithic deposits, and yet they are actually passing into the other condition, which is the worst state of the two.

The sediments are sometimes seen to be mixed. You have occasionally lithic acid and the lithates in the sediment, and the phosphates also at the same time; so that the whole state of the patient may be one of transition. You will sometimes find that these conditions alternate, so that you may be very much puzzled, perhaps, in the treatment of the case.

Urea abundant in Phosphatic Urine.—Where the urine is abundant, pale, green, and alkalescent, and the phosphates are deposited, it is observed also that urea is in

great abundance; but Dr. Prout considers that it is imperfectly formed — that it is the urea which gives rise to the abundance of ammonia, and the way in which this operates he conceives to be the following:—In these cases the urea is secreted in abundance: urea, you know, is a compound, and being badly formed, it undergoes some change, and affords ammonia: as there is not a correspondent quantity of phosphoric acid, this ammonia precipitates the lime, and then by uniting with the phosphate of magnesia a triple salt is formed, which is called *ammoniaco-magnesian phosphate*. This is of course a phosphatic sediment, and you may easily know this triple sediment by the white glistening particles. You see why the urine in these cases is alkaline: it is because there is such an abundance of imperfect urea giving rise to so much ammonia.

However, though the abundance of ammonia from the diseased urea may be the cause of the deposition of this phosphatic sediment, yet the same effect will be produced from a deficiency of acid in the urine. If there be not sufficient phosphoric and sulphuric acid, the lime will be precipitated, and not only the lime, but the ammonia and magnesia, so that you have *ammoniaco-magnesian phosphate*. Sometimes it is said that an excess of lime is the cause of the mischief; that, however, is rare.

Thus you see that the urine may err through an excess of acid of one kind or other, but generally it is from the presence of nitric acid; or it may err from a deficiency of the acids.

The sediments are sometimes mere powders, called *amorphous*, but sometimes the matters deposited are in a crystalline state; and in the latter case they may, in the first place, be red.

Lithic Acid.—Now these red, granular, crystallized sediments (to distinguish them from powdery ones) are spiculated crystals. You may see them in the urine. There will be red crystals frequently with numerous spiculæ at the bottom of the vessel; some of them by chance may be swimming, and some may be sticking at the sides. These are very nearly pure lithic acid: most probably from the great quantity of nitric acid, the lithic acid is precipitated. Sometimes the lithic acid is absolutely in excess, so that it is not held in solution, and therefore crystals are deposited; but this is not necessarily the case. If you take urine, and add acid to it, the lithic acid will be precipitated; and therefore when you see a red sediment crystallized with spiculæ, you know that it is nearly

pure lithic acid; but it may arise rather from the lithic acid being too abundant, or some acid being present in the urine which causes precipitation. The phosphoric acid will sometimes do this, and sometimes the sulphuric, but frequently it is muriatic acid, and sometimes it is said even to be carbonic acid. It must be a weak acid or an acid of weak strength to precipitate the lithic acid, because any strong acid will produce decomposition. The urine, when you see this spiculated, crystallized, red sediment, is usually very transparent, and of a fine, reddish colour.

Ammoniaco-Magnesian Phosphate.—If the crystallized sediment be white, it is usually the triple phosphate of magnesia and ammonia, and it is called “*ammoniaco-magnesian phosphate*.” The urine here is just the same as if the sediment had been in powder: it is alkaline, abundant, pale and greenish, and soon becomes ammoniacal, and decomposes.

Oxalate of Lime.—You may have crystals consisting of oxalate of lime, and then the crystals are of a dark green colour, and the urine is found to be acid; but this is a very rare occurrence, and one which I have never seen.

The crystallized deposits are said never to be found together;—the powdery concretions, the amorphous ones, sometimes are.

URINARY CALCULI.

Now if it happens that these crystals are larger, or that more solid matter is heaped together, we give to them the name of *concretions*. It is merely the same thing on a large scale, perhaps the union of several of these, deposit over deposit, and a great quantity of solid matter. You may be prepared to understand these concretions from what I have now said respecting sediments, both powdery, amorphous, and crystalline.

Lithic Acid Calculus.—In the first place we have a concretion which is merely lithic acid, and is of a brownish red or fawn colour. They are sometimes smooth, but sometimes they are tuberculated, rather rough. If you divide them, you find that they consist of concentric laminae within. If they are broken, not sawn, the fracture is imperfectly crystallized, and of a deep fawn colour, like the rest. Sometimes they are not in concentric laminae, but they are an amorphous irregular mass, without plaits, and pale; but when they are pale, they are generally mixed with a little phosphate, or even a little oxalate of lime.

Chemical Characters.—Now if you take this calculus and apply heat to it, it becomes white, and burns away, and leaves a minute quantity of white ash, which is generally alkaline. This calculus is quite

soluble in potash, and you may precipitate it again by any acid. It descends in the form of a white powder. If you add nitric acid with the heat, it is dissolved, and on drying it you have a fine carmine colour, which is erythric acid. I before stated that when nitric acid is added to lithic acid a fine scarlet colour is produced, and therefore if you take such a calculus as this and add strong nitric acid to it, then you have a red colour.

Lithate of Ammonia Calculus.—But this calculus is rarely found pure: it is generally mixed with the lithate of ammonia, and it is then clay coloured; rather paler than the other. It has, however, the same general character: it is sometimes smooth and sometimes tuberculated; sometimes it has concentric plaits, and sometimes it is an amorphous irregular mass; but it is more rarely found in the latter state than the calculus of pure lithic acid.

The most common calculus of this description is one not of pure lithic acid, nor pure lithate of ammonia, but a mixture of both, and therefore whenever you see a calculus of the description I have now mentioned, you cannot say whether the ingredients consist of one or the other; but in nine cases out of ten, it will be found to be a mixture of both.

If lithate of ammonia exist in it, or if it be pure lithate of ammonia, it decrepitates by heat; and if you add potash with the heat, you soon have ammonia given off. It is soluble in the alkaline subcarbonates; whereas a pure lithic acid calculus is not, and therefore you may easily distinguish the one from the other by chemical means.

A calculus, consisting of pure lithate of ammonia, occurs generally before puberty, and is small, and rather uncommon. The most usual thing is to have lithic acid and lithate of ammonia.

The lithate of ammonia calculus is not only continually found mixed with lithic acid, but it is often mixed with oxalate of lime.

Oxalate of Lime or Mulberry Calculus.—The next calculus which is found in acid urine, is oxalate of lime. This is for the most part very easily known. It is a brown rough calculus: it is exceedingly hard, and generally exceedingly rugged. It is called a *mulberry* calculus, from its irregularity on the surface. Sometimes it is nearly black.

If you apply heat to it, a white efflorescence appears upon it, and from this circumstance you decompose the acid, and oxalate of lime no longer remains, but pure lime, and this being alkaline, it will stain turmeric paper. Occasionally this calculus has been found smooth, but it must be a very small size indeed

to be smooth. Generally it is a most formidable looking calculus, such as would make one shudder, when you remember it is formed in the human bladder. It is known by its ruggedness and dark colour.

Cystic Oxide Calculus.—There is another calculus which exists with acid urine, which is called *cystic oxide*. It is so very rare that you will, perhaps, never meet with it; but I will describe it. This kind of calculus is of a yellowish white colour, and smooth externally. Internally, it is a confused, crystalline, glistening mass. In point of size, it is small.

If heat be applied, a peculiar odour is emitted, and it is soluble both in acids and alkalies.

Phosphate of Lime Calculus.—We now pass to the consideration of other calculi, which exist with urine, deficient generally in acidity, and sometimes bordering very closely on alkalescency. These are the phosphates, and the first of which I will speak is the phosphate of lime calculus. This calculus is of a pale brown or white colour: it is very smooth and polished; it has regular plaits, which are very separable from each other; it is rare and small; and it is thought by Dr. Prout not to be a true urinary calculus, but to be formed in the prostate gland.

It is not fusible by the heat of a blow-pipe; and when you dissolve it, you may precipitate it again. Although this is not dissolvable by heat, yet you may dissolve it in muriatic acid.

Triple Phosphate of Magnesia and Ammonia Calculus.—However, we have another phosphate which, unfortunately, is very common, and this you may know in a moment: it is the triple phosphate, consisting of phosphoric acid, magnesia, and ammonia. This is white: it has no laminae, and is easily pulverized or broken. This calculus consists of the same substance as the white sand I mentioned: it glistens, and consists of a number of minute, white, sparkling crystals: the surface is uneven; it is covered with minute asperities.

If you apply heat or potash to this calculus, ammonia escapes, and therefore your chemical knowledge will enable you to say what it is. If you apply intense heat to it, it will at last melt; but this is effected with great difficulty. It is more soluble in acids than the phosphate of lime, and you may precipitate it again in the form of minute shining crystals. In consequence of the addition of ammonia, it is called a triple phosphate.

Fusible Calculus.—Then we have another calculus which is very common, but not quite so common as the first of which I

spoke. This is a compound of the last calculus I mentioned and the last but one: it consists of phosphate of lime united with the phosphates of magnesia and ammonia. It passes under the name of the *fusible calculus*, because it so easily melts under the blowpipe. You may know this calculus in a moment, by its breaking under your fingers like so much chalk. If you rub it on your sleeve, the coat is immediately dirtied as it would be by chalk. It is exceedingly white and very friable. Generally, it is not laminated, not in plaits; but if it be separable into laminæ, you generally find the triple phosphates between the laminæ, in the form of shining crystals. When it is not laminated at all, but is a mass like chalk, it sometimes attains a very large size.

It is very soluble in the acids, particularly diluted muriatic acid, and it is a calculus which frequently gives the surgeon a good deal of trouble, coming to pieces when he applies the forceps, just as any mass of chalk would do. You may easily separate the lime from this calculus: by adding oxalate of ammonia, the lime goes to the bottom; and then again the magnesia may be separated by adding pure ammonia.

Alternating Calculus.—However, we do not have this calculus often in a form so simple as that I have now mentioned; but very frequently, indeed, we have what is called an *alternating calculus*: that is, a calculus consisting of these various substances in different layers. In by far the greater number of these cases, you will find that the inner substances are those which I first mentioned—lithic acid, or more properly speaking, a compound of lithic acid and ammonia or oxalate of lime, and then in the outer part you find the phosphates.

The layers of these alternating calculi may be very various; but generally the nucleus, the internal portion, consists of lithic acid or oxalate of lime. When a patient has a mulberry calculus, nature at last throws the phosphates around it: it becomes white externally, and loses a great portion of its roughness, so that the patient does not suffer so much as before. The external crust generally consists of a fusible calculus. Sometimes you have laminæ of all the three ingredients; but still the external crusts generally consist of the phosphates. When calculi are thickened this way, they are often very large.

Chemical Characters.—As to the chemical qualities, they depend upon the layer you examine. If you inspect the outer layer, you find all the characters of the phosphates, and within there are all the characters of lithic acid and ammonia.

Mixed Calculus.—Then, again, we have another compound calculus, in which the materials, instead of being in alternating

layers, are all mixed together. Generally, however, when you see a mass of this kind, it does not consist of a mixture of oxalate of lime and other things, but lithate of ammonia and the phosphates, and then of course the colour will vary with the composition. Accordingly as lithic acid predominates or the phosphates, so will the calculus incline to a clay or white colour, and the proportions are quite indeterminate. A mixed calculus of this description is generally very hard, seldom laminated, and seldom large.

Carbonate of Lime Calculus.—There is another calculus, called the *carbonate of lime calculus*, because it consists of pure carbonate of lime. It is very rare and very friable.

It has all the characters of chalk, and effervesces with the acids.

Xanthic Oxide Calculus.—Then there is an eleventh calculus, which is so very rare that it has only been seen once: it is called *xanthic oxide*.

The substance of this is very peculiar, and by the addition of nitric acid it becomes yellow.

Fibrinous Calculus.—There are some concretions of the bladder which have turned out to be nothing more than fibrin.

Prostate Calculus.—Then, besides these urinary calculi, we have calculi in the prostate, and they are found in two situations: first, in the natural cavities of the gland; and then they are of a yellowish brown, more or less round and small. Sometimes, I believe, these come from the kidney. I have passed thousands of these at different times, about the size of pins' heads. I have collected some and shewn them to Dr. Prout, who says they came from the prostate. But calculi are sometimes found in an abscess of the prostate; and these are much larger and highly polished, and they are chiefly phosphate of lime; and Dr. Prout believes that the phosphate of lime calculus found in the bladder really is a prostatic calculus.

NOTES OF LECTURES,

BY THE LATE

DR. JAS. GREGORY, OF EDINBURGH,

On Dyspepsia, Hypochondriasis, and Chlorosis:

Taken in Short-hand, in the years 1819-20,

BY EDWARD BLACKMORE, M.D.

Resident Physician in Bath.

[Continued from page 737.]

Process of Digestion.—Fermentation goes on in the human stomach; a mixture of

animal and vegetable food more rapidly ferments than each singly(?); eructation throws up the sweetish or sour matter. The saliva is understood to retard fermentation: does it do so more than water? By mastication, there is a thorough admixture of the matters; a mass of small particles being moistened, is taken down into the stomach, diluted by the saliva and the gastric fluid. In the sedentary and literary, swallowing the meat without chewing it leads to bad consequences. From "bolt-ing bacon," people think they can work longer than without it.

The pylorus is raised in digestion, and thus the mass is retained in the stomach. In three or four hours it is transmitted into the duodenum.

Cold-blooded animals digest as well as the warm-blooded do. In the most healthy stomach slight fermentation always occurs. See Dr. Rush's Thesis. He took various kinds of food, and then an emetic; and though he took alkali he always found fermentation. Yet it is said that no flatulence, no acidity, is observed where digestion is perfect. Digestion was thought to depend on fermentation. In the fowl there is a muscle with a cartilaginous lining termed the gizzard: the animal will swallow small stones to facilitate the process of grinding.

The human stomach has longitudinal and circular muscular fibres. Dyspepsia was thought to be from weakness of these fibres; the stomach could not evacuate itself; the matters would remain long in it. This would be a part of the proximate or pathological causes of dyspepsia. From the long retention of the alimentary mass by a scirrhus pylorus, it will ferment in spite of the anti-zymic power of the gastric juice: the bile prevents fermentation in the intestines.

Digestion chiefly depends on the chemical operation of the gastric fluid. In some creatures this fluid dissolves animal substances; in others, herbiferous vegetables; in others both—as in omnivorous animals. Leather has been dissolved. Bones also were given to a dog, yet no bone was found in the feces, or in the animal. In a certain case balls of ivory were swallowed, aliment being inclosed in them: the balls were partially dissolved. Metallic balls were given; they were not dissolved. See Dr. Steevens' Experiments.

A vitiated quality of the gastric fluid occurs in dyspepsia: an immense quantity of mucus is vomited; sometimes a thin watery matter (termed pyrosis, water-brash), the stomach being quickly filled with it. Sometimes there is a diminution in the secretion of the gastric fluid.

The succus gastricus was thought to

dissolve the stomach itself, as, soon after death, holes have been found in it.

Physiological Causes of Hunger.—Some maintain the theory of a contraction of the circular fibres of the stomach occasioning hunger; but a circular section is always preserved—the sides do not rub on each other. Emptiness of the stomach does not produce hunger. Depletion of the vascular system will produce it, and sweating.

The proximate (or pathological) causes are, weakness of the muscular fibres of the stomach, and a vitiated secretion of the gastric fluid.

The stomach is weakened by over-distention, called a "surfeit:" few stomachs, however, are so weak as not to be able to support life. People might be cured of dyspepsia by regulating the quantity they take in. They fancy it is hurtful to allow the stomach rest—that is absurd. The luncheon is now a serious meal; a little milk, or soup, and bread, is well enough. Allowing the stomach to contract, as it should, is the best thing; over-distention will bring on dyspepsia. A draught of ℥ij. of milk, or of water-gruel, will disorder the stomach of some people.

Remote causes resumed.—*Repletion and improper diet.*

The stomach being overloaded with different kinds of food, nausea, vomiting, oppression, eructation, heartburn, and fermentation, are produced. Taking improper food, that is difficult of digestion, or disagreeable to the constitution, or even loading the stomach with wholesome food, is equally the cause of indigestion.

Eat not a variety of articles at one meal; you will eat more than is proper. Some absurdly eat a little of every thing at table. All food difficult of solution is difficult of digestion; some food remains in the stomach for weeks, and keeps up dyspepsia, as ham, bacon, tongue, salmon. All fat oily things are difficult of digestion. Every one after a debauch is dyspeptic. One used to eat heartily, and drink much punch at supper; the next morning his head shook violently; he then used much exercise, and ate little at dinner. They counteract it by taking spirits in a morning, which makes it worse.

Idiosyncrasies.—There are idiosyncrasies, peculiarities of digestion.

Some will not digest milk, which is in general the mildest food used; yet a small quantity may disagree. One could not take a little coffee, or cream, but it operated like jalap. Eggs, hard boiled, are difficult of digestion; soft boiled eggs are good, yet they will disagree with some per-

sons; and even eggs in biseuit are discovered by the indigestion they produce.

Some cannot bear fish, as salmon, or shell-fish, muscles, crabs, though in general they are easy of digestion. Some cannot take honey, which was introduced by the Arabians; a little has produced gripes and purging: so of strawberries, cherries, &c. (The odour of orange marmalade in a certain lady induced vomiting. New bread, and coarse oaten cakes, will disagree with some persons.—E.B.)

People digest the food to which they have been accustomed, as sailors.

Fasting.—Some lose their appetite by waiting beyond their usual meal time.

Sedentary habits.—An indolent, inactive, sedentary life, begets dyspepsia and hysteria. (We see it in shoe-makers, lace-workers, clerks, &c.) Bodily exercise is the great subsidiary power to the circulation of the blood. The most eminent literary men among the ancients were remarkably healthy. Socrates used to carry arms. Plato (πλάτων, broad, is the origin of his name) was a man of immense stature. Xenophon was a man of great activity. (Dr. Gregory once carried a musket as an Edinburgh volunteer; so did Dr. Samuel Johnson.) In the colleges of the monks literary pursuits were first combined with bodily inactivity. It weakens not only the body, but the intellectual functions also, impairs the nervous system, and unfits for study and exertion. (Reading shortly after dinner is bad; see Dr. Paris.—E.B.)

If you bestow the whole of your time on your studies, you will not understand and remember; in devoting twenty hours a day, you would make no progress. More progress is made by reading eight hours a day than eighteen. Variety of study is almost, but not equally, like desisting from study; (e. g. in Priestley and Bayle.)

Mode of reading to profit.—In reading, I mark thus (+) what seems true; thus (—) what is false; and thus (?) what is to be inquired into.

Passions of the mind destroy the appetite, and cause dyspepsia. For example, the depressing passions, fear, grief, anxiety; also joy, love, ungratified sexual appetite. Venery is another cause. Pain is also a cause.

Cold with moisture is another cause; it checks perspiration, impairs the appetite, and causes indigestion. People being advised to go into a warm climate are relieved of stomach complaints. They also escape by wearing flannel next the skin. (See my statistics in the Edinburgh Medical Journal for 1831, for the places and seasons where stomach complaints prevail. One species is designated, from this cause, dyspepsia pyrosis—*suecica*. Extreme heat is also a cause, as in bakers.—E.B.)

Narcotics induce the disease. Tea is injurious; it is not merely the warm water, yet warm liquids are hurtful. Some take coffee with impunity, whose stomach is disordered by tea. I find green tea makes my hand to tremble, and causes palpitation; whereas other kinds of tea have not that bad effect. It will prevent sleep, and for that purpose was introduced among the Chinese. He is learned among them who knows 20,000 of their letters; they say they have 80,000. Men of letters among them must be apt to fall asleep. The compositions of spurious tea are the next thing to poisons. Some, however, bear tea better than coffee.

Sialogogues.—Tobacco and snuff bring indigestion. The saliva is not to be spit out; it assists digestion. To spit it out is hurtful to the stomach.

Opium weakens the stomach and the whole constitution; as in the Turks. People get into a bad habit of taking it at bedtime; weakness and vomiting are the effects. I got asthma and catarrh from leaving off the flannel next my skin in summer. The tincture of opium put off a fit of asthma, but afterwards made me very weak. People who are used to take frequent opiates are subject to very obstinate stomach complaints. (See Dr. Christison's paper, Edinburgh Medical and Surgical Journal, 1831.) The Mahomedans take a dose of opium, three pills before sunrise, which serves them for the whole day.

Aromatics, when long continued, weaken the stomach, as pepper, high-seasoned soup, &c. It is a law of the animal economy, that excited action weakens a part. Bitters also, if long and freely used, do harm. People will vomit by infusion of chamomile; so gentian in excess prolongs the complaint.

The continued habit of vomiting will occasion dyspepsia. Julius Cæsar used to take an emetic by way of preparation for a good dinner. (Dyspepsia from mineral poisons, lead, mercury, antimony, &c. as in gilders, painters, type-founders.—E.B.)

SECT. V.—The Cure.

There are (1) preservative; (2) palliative; (3) curative indications. 1, To remove the remote causes; 2, to relieve the symptoms; 3, to restore the tone of the stomach.

(More correctly two *consilia medendi*: 1, to palliate symptoms; 2, curative, to remove the causes, remote and proximate. Dr. Gregory does not give distinct *consilia medendi* for the different forms of the disease; his views of the treatment were influenced necessarily by the class of patients he met with, who were chiefly the affluent and studious.)

(1.) You must attend to the causes; the

disease cannot be cured by any medicines (alone). Avoid or remove the *potentie nocentes*. "Who," it has been asked, "is a perfect physician?" He who can distinguish what can from what cannot be done. I never saw one patient cured by medicine; but hundreds by attention to regimen. The remote causes must be attended to and removed, before you can cure the disease. People run about to different physicians. In the symptomatic species cure the primary disease.

Regimen, as to meat and drink.—People might be cured by regulating the quantity they take in. Nothing is so good for a weak stomach as to give it full time to do the work, and time to rest itself; this is of more consequence than all the tonics in the world. Allowing the stomach to be empty for some time is useful to its tone, and promotes the proper secretion of the gastric juice. Many would get rid of the disease if they would only take half of what they usually eat, and avoid such meats as are difficult of digestion. Other physicians will have you live on animal food; people suffer from it; they have tried it for months, abstained from vegetables, taking only a little bread, and the stomach complaints were as bad as ever. Never one succeeded by so doing. (One patient kept turtle soup on his stomach when other food was vomited; another retained only toasted bacon.—E.B.)

The mixture of animal and vegetable food is best; the former alone is too stimulant. I say, "take a little of the vegetable if well boiled, but let the stomach never be loaded." Some are cured by living wholly on vegetables; I would not recommend that altogether.

Fermented bread is more easily digested than unfermented, as oat cakes; yet oatmeal is more digestible as porridge, while the oat cake disorders the stomach; (so will bran bread sometimes, which is so often recommended. The Abernethy biscuit, which is composed of the finest flour and magnesia, is good.—E.B.) Unfermented wheaten cake is difficult of digestion; new bread is worse digested than stale; dry toast and biscuit are digested, while hot rolls are bad.

People take raw oysters to get an appetite; they had better abstain from the oysters and the dinner also. Soland goose, or gunnet, is also used to give an appetite, by stimulating the stomach. I have a strong objection to all fish-sauces.

A proper allowance of food is requisite; a dry or furred tongue is not always a reason for low diet. (Early dinners are of great importance.—E.B.)

Drink.—They should abstain from ascetic wines, as claret. You must scarcely ever allow distilled spirits; occasionally it

may be proper to give brandy, but never as a common drink. A glass of cold water is better for promoting digestion than a glass of wine or brandy. Tea or coffee in moderate quantity is innocent for them.

Air, exercise, and diversion.—Cool air is good; people are weakened by confining themselves in-doors, in their warmth. Cold weather gives appetite, as is seen in the Greenland whale fisheries. Horses also that are much exercised in the cool air, eat much. Much weight is lost by insensible perspiration in cold weather; this is a cause of hunger. One used to walk till he could eat a crust of bread with appetite. (Friction, gymnastics; see Sir A. Falconer on the broad-sword exercise.)

Regular exercise gives strength, and promotes the excretions.

Amusement.—(The moral management is important; the hope and confidence of the patients are useful; hence the success of certain eminent physicians in the use of very ordinary remedies—"foi est tout."—E.B.) Withdraw their attention from their own complaints; they really make them worse; have some engagement for them, as travelling. It is absurd to determine not to think about the complaints.

The benefit from the watering-places is from the amusement, and being in cheerful company: the faith of the patient is essential to his perseverance, and cheerfulness of mind is healthful; a little deceit is necessary! Mental impressions will cure the malady.

Emetics.—You may give an emetic if undigested matters lodge in the stomach; some think that emetics promote a healthy state of the gastric fluid. They will break the morbid train of symptoms in fevers. Ipecacuanha is better than antimony (alone). Be cautious of this practice. I would not bring the mass up by an emetic, but carry it downwards by a purgative. You may sometimes give an emetic to clear the load: where oppression and nausea exist, they are proper. Give ipecacuanha with tartarized antimony, to excite speedy vomiting; as less injury is done by it than by long nausea. (This is particularly bad in the gouty subject.) An emetic will give temporary relief in stomach complaints; but in general avoid it, for frequent vomiting weakens the stomach.

Purgatives.—You also give purgatives, but not such as are too strong (worm-medicines do harm); the milder purgatives will do—even magnesia will be cathartic if there is acid on the stomach; (Henry's is preferable—the common is bad and irritant). Proper purgatives will clear the stomach; too much purging is weakening. Use the sulphate of magnesia and soda, or magnesia three parts, rhubarb one part, ginger half a part. To give a

moderate dose and repeat it at intervals, is better than larger doses given at once. Jalap offends the stomach, although it is better in dropsy as a hydragogue. If medicine, however, be made too agreeable, patients will take it too often, which is bad; especially for dyspeptics. Give the pil. rhei comp. or pil. alois c. sapone, or alois c. rhei, in a liquid form (e.g. decoct. alois comp. Lond. Pharm.) The pill colocynth. comp. is excellent: if it is violent, take less of it; it is not apt to gripe. If object to rough purges, as elaterium, as I do to rough emetics; they weaken the body much. The dyspeptic are much relieved by the Cheltenham waters; and in liver complaints it counteracts the effects of full living and want of exercise. I give sulphat. magnesiæ, ʒj. in a glass of water every hour until it operates. Regular motion of the bowels is necessary to good appetite; it promotes the vigorous peristaltic action of the stomach, which is necessary to empty it in proper time.

Alterants: Mercury.—Avoid calomel. I do not think it such an “excellent remedy” for people who have “too much bile,” or “too little bile,” or “no bile at all.” (Did not Gregory undervalue mercury? The pil. hydrarg., hydrarg. c. cretâ, calomel with soda, will often relieve when all other medicine is inefficacious. See Dr. W. Philip. But it will hasten ulceration of the stomach in some cases). They give an alterative course of mercury: they suppose they can correct the bile by it (spoken in a tone of sarcasm). This is an erroneous hypothetical notion; guard against the practice.

(In the chlorotic it will induce dysentery.)

Antacids.—If the symptoms of acidity be severe, such as acid eructations, vomiting, spasms, heartburn—you give alkaline salts, or earthy; as magnesia, one or two scruples. If this is violently cathartic, give chalk, with aromatic powder. It corrects the acid and checks diarrhœa. Dr. Cullen thought, that by correcting the acid the cathartic process would be hurried on; this is mere speculation. (“Nulius addictus in verba jurare magistri,” truly belongs to Gregory.) The heartburn is relieved by absorbents and alkalies. All the medicines useful in lithiasis, are those that correct acidity—as alkaline salts, liquor potassæ, &c. People, on using the quack medicines, have been relieved; they desisted from them, and their complaints returned. Magnesia is the best medicine, when used so as not to purge excessively.

The London carbonas potassæ is good for the acid; it neither purges nor occasions costiveness, as chalk does. It is so mild that it may be laid on the tongue, or

washed down with water. Much of the subcarbonate cannot be taken by the stomach; it will neutralize the acid, it is decomposed, and comes up, causing a pungent sensation, with an explosion. (Cautie alkali, even Brandish's solution, is sometimes hurtful.) To correct the acid is a great article of cure. Acid and bile in the stomach are weakening causes.

Ammonia will correct the acid, but it is too stimulant; yet, in croup, as in gastrodynia, it is useful. (Tinct. valerianæ ammon. is good.) (Dr. Blackall told me that he found lime-water, with milk, very useful in cholera; it allayed the vomiting.)

Aqua calcis, lime-water, is very useful: there is only one grain of lime in one ounce of it. One drank 1b1500 in two years!

Tonics and Cordials.—I have very little confidence in them. I give them because others do, and the patients would think themselves neglected without them. I trust to the regimen. It is allowable to deceive them for their own benefit. Saline or aromatic stimulants are used. Some cannot digest their food without much common salt—the muriate of soda; it assists digestion by its stimulus to the stomach, thus promoting the secretion of the gastric fluid. So does vinegar. Some think aromatic sulphuric acid astringent, and good for laxity of the muscular fibre; I do not rely on the speculation, but try the most celebrated tonic. (I have found nitro-muriatic acid and calumba very useful.—E. B.) A moderate use of aromatics for a short time, may be good for exciting the stomach to expel the matters, therefore I allow a small quantity of the plainest food with a little salt and mustard. In a household book of the Duke of Northumberland, for A.D. 1500, one hundred and fifty gallons of mustard were set down annually for his family.

(Cubebs cured some of my patients.—E. B.) Armoracia, horse-radish, is not to be used constantly.

Bitters are not to be trusted to for restoring strength, to the neglect of regimen. Gentian, calumba, chamomile, are used; the strengthening effect is limited, and long use of them will weaken the stomach (and inflame the mucous membrane). I never go on with longer than four weeks. People declare that the stomach has been relieved by bitters: they are used for the gout, which depends on disorder of the stomach; they prevent the gout. Dr. Heberden speaks favourably of them, yet Dr. Cullen says that no one lived three years after being cured of gout by them! I would give them in moderation. I give carbonate of potass, with cinnamon or peppermint water, and tinct. gentian. comp.

They complain much of flatulency: a little sulphuric æther produces a great discharge of flatus. It is a most powerful stimulus; so is a mixture of tinct. card. arom. aq. cinnam. and spirit. ammon. arom., or the carbonate of ammonia and assafœtida: *e. g.* Mist. Assafœtidæ, ʒss. Sp. Ammon. Arom. ʒss. will relieve pain. (Chlorine, the Bath waters, and iodine, were not noticed by Gregory.)

Cinchona has answered well: *e. g.* Pulv. Cort. Peruv. ʒss. bis die, or

R Decoct. Cinchon. ʒj.; Acid. Sulphur. Dil. ʒj. M.

I object to giving a full dose of the tincture, it is as bad as a dram. (Quinine was not then in use.—E. B.)

R Carbon. Ferri, Extract. Cinchonæ, partes æquales (or Sulph. Sodæ, Carb. Sodæ, Sulph. Ferri, et Tr. Gentian, in chlorotic dyspepsia.)

Iron will make the stools black. Mineral-iron springs, as at Tunbridge, Scarborough, Peterhead, are useful, by washing out the urinary passages: washing out the whole system by a large quantity of water is good. (Diuretics, as colehiæum and taraxacum, I have found very useful in some stomach complaints; particularly good in chronic inflammation of the mucous membrane, but bad in spasmodic affections of the muscular and villous coats.—E. B.)

The oxide of zinc is used as a tonic, and the subnitrate of bismuth, gr. v.: it is not better than others.

Murias calcis is a tonic extolled for scrofula; and murias barytæ, of which I gave 100 drops, and produced vomiting. Tinctura ferri muriata and ammoniata are used. Dr. Fothergill says that the best effect was from their loading and disordering the stomach, so that the patients would not take so much food; and this relieved the complaints. (They create erythema of the mucous coat.)

(Nitrate of silver and balsam. peruv. have been used successfully by me.)

Sea-bathing was good in a case of urgent thirst, from a morbid state of the stomach. Cold water on the surface of the body is a powerful tonic; the shock is a stimulus; if long applied it is a powerful sedative. It gives a keen appetite. It is only the transient application of cold that is good: if the patient remain cold, you must suspend the remedy.

Diaphoretics.—There is great sympathy between the skin and stomach: nausea and vomiting are relieved by promoting perspiration. Rubbing with oil was a part of the ancient regimen for preserving the health: the friction promotes the strength of the muscles and perspiration.

Tepid bathing is useful in dejection of spirits. Use it, and gradually bring it to the cold-bath: the former is salutary for both the dyspeptic and hypochondriac. A very hot bath is hurtful in apoplectic cases; in the paralytic also it is too stimulating.

Narcotics.—Opium: you will relieve pain by it, after correcting the acidity. Dr. Cullen recommends it in pyrosis.

(The pil. sapon. c. opio is good, if the secretions of the stomach are excessive. I once met a gentleman who said he had taken 400 grains a-day: he shewed me a box of four-grain opium pills, four of which he at that time took daily after dinner. See the Confessions of an Opium-Eater. The prussic acid had not come into use at the time of Gregory's lecturing. I have proved its great virtue in dyspepsia. Counter-irritants on the epigastric are powerful remedies. The emp. cumin. co. cured a dreadful periodical attack of gastrodynia in my own person, brought on by the habits connected with travelling in Italy, in the year 1823.—E. B.)

ANALYSIS OF THE FLUID OF A HYDROCELE.

To the Editor of the Medical Gazette.

SIR,

You will oblige us by inserting in your journal the following analysis, which we have just completed, of the fluid of a hydrocele, curious from the fact that rather a considerable quantity of cholesteroline was detected in it; and although M. Breschet and Dr. Christison have both noticed its occurrence in this as well as other morbid secretions, still we believe no detailed analysis has yet been published.—We are, sir,

Your obedient servants,

R. H. BRETT,
GOLDING BIRD.

Guy's Hospital, August 30, 1833.

The fluid in question was of a dark grumous appearance, with brilliant crystalline lamellæ floating through it: these last subsided to the bottom of the containing vessel on repose. It underwent coagulation by boiling and the addition of nitric acid, as also by acetic acid and the ferro-cyanuret of potassium. When a portion was coagulated, and the dry mass resulting from the continued application of heat treated with

boiling distilled water, the whole filtered, and the aqueous solution evaporated to a few drops: the subsequent addition of nitric acid caused no play of colours, indicative of the presence of biliary matter. When a portion of the fluid was thrown upon a filter, the thinner portions passed through very slowly: after the filter, with its contents, had been dried, the paper was found to be stained of a reddish brown colour, similar to that produced by stains of blood of long standing. After continued washing, the crystalline residue was freed entirely from colour, and exhibited the following properties, of a brilliant white colour, consisting of distinct crystalline plates, requiring a temperature of 267° F. for its fusion; soluble in ether and alcohol; not soluble in caustic potass or water; undergoing solution, with the evolution of nitrous acid fumes, when boiled in nitric acid, and yielding by evaporation an orange-coloured, brittle, and readily fusible mass, soluble in alcohol, and crystallizing in needles by spontaneous evaporation (the cholesteric acid).

500 grs. of the fluid, without filtration, were evaporated over a water-bath to dryness, and the residue found to weigh 58·5 grs. leaving 441·5 grs. for the weight of water. The coagulated mass was then boiled in five or six times its bulk of alcohol, the whole rapidly filtered, and the filter well washed with boiling alcohol; the filtered fluid and washings were then evaporated to dryness, and the resulting mass found to weigh 6·3 grs. This was boiled in a solution of caustic potass, and filtered: what remained on the filter, after being well washed and dried, was in the form of white crystalline plates, weighing 5·4 grs., leaving ·9 for the weight of animal matter and salts dissolved out by caustic potass and water: the salts were found to consist of alkaline sulphates, chlorides, and phosphates. The albuminous extract, after being thus treated with alcohol, was boiled with a considerable quantity of distilled water, until nothing more could be taken up. The aqueous filtered solution yielded by evaporation an extract weighing 1·3 gr.: this, when ignited, left a saline residue weighing ·37, which, deducted from 1·3 gr., gave ·76 as the weight of animal matter soluble in water. The salts removed by water were of the same character as those previously removed by

alcohol. 500 parts of the fluid consisted, therefore, of

Water	441·50
Albumen and colouring matter of the blood	51·07
Cholesterine	5·40
Animal matter and salts soluble in alcohol	·90
Animal matter soluble in water . .	·76
Salts	·37
	<hr/>
	500·00

RECLAMATION.

To the Editor of the Medical Gazette.

SIR,

In the last number of the Medical Gazette it has been asserted that I considered the crystallization produced in a solution on the addition of nitric acid, to form the only test to be relied on in the detection of urea. Now my words were as follows:—"Crystallization on the addition of nitric acid, has been used in these researches as the principal and most indispensable test." I am sorry to observe so unpleasant a representation of the original text. A reference is also made in support of an assertion, which I have never cast any doubt upon, viz. that the presence of urea in the blood has been supposed the cause of the peculiar symptoms manifested in anasarca with coagulable urine. Now all that I said was, that urea had never been declared present in every case of the above description, which is quite compatible with the former opinion, since these peculiar symptoms (such as head affection, &c.) though always to be dreaded, are far from being present in every such case of anasarca.

As regards the crystallization which your authors say the fatty matter of the blood is capable of producing on the addition of nitric acid, I never was fortunate enough to observe it, and from my own experience am convinced that although nitric acid does not materially interfere with the crystallization of stearine from the warm alcoholic solution, I am very confident that any portion of fatty matter remaining dissolved in cold alcohol, is quite incapable of affording any reaction which can be confused with the crystallization of urea; and even were this the case, there are marks of distinction which cannot be well over-

looked. The nomenclature used by these gentlemen is highly inadmissible, for since the stearic acid does not enter into the constitution of human fat, the term nitro-stearic, applied to an acid procured from the human subject, is decidedly objectionable.

In conclusion allow me to remark, that I have procured urea from blood by the digestion of water on the dried alcoholic extract, which entirely sets aside the confusion which it is imagined might arise from the presence of fatty matters.

By the insertion of these few remarks, you will much oblige

Your obedient servant,

G. O. REES.

Guy's Hospital,
Aug. 27, 1833.

CASE OF RUPTURE OF THE DUODENUM.

To the Editor of the Medical Gazette.

SIR,

You will oblige me by recording this case in the pages of your valuable publication.

I am, sir,

Your obedient servant,

J. COLLIER,

Member of the Royal College of Surgeons.

Brackley, August 29, 1833.

William Baldwin, aged 13 years, was on Saturday morning last attending to the work of a horse churn; and, whilst making water, unluckily placed himself with his back to an adjoining wall. The pole of the machine in its rotation, coming towards him, gave him a very severe blow on the abdomen, in the umbilical region, causing a most excruciating sensation. He was instantly taken up and carried into the house, and, as soon as he could speak, said he thought it would have burst him. Shortly afterwards he vomited, for which he drank brandy and water; and after a time, being somewhat relieved, expressed a wish to go home, a distance of a mile and a half. He walked the first mile with being led, but was obliged to be carried the last half-mile. He told his parents where and in what manner he was hurt. His symptoms not being urgent, the friends delayed calling in any assistance; he was therefore put to bed, and remained there two or three hours.

At two in the afternoon he got up, dressed himself, and walked down stairs, and stayed till seven o'clock; now being fatigued, he returned to bed. During the day he had frequent vomitings of watery fluid; the stomach rejected every thing; and in the evening he brought up bilious matter. At eleven o'clock a sudden collapse ensued; the friends were alarmed, and sent off for medical aid. I visited him directly, but he expired before my arrival, having survived the accident thirteen hours.

On inquiry, I learnt he had neither vomited blood, nor passed any by the rectum; indeed the bowels were not evacuated since the receipt of the injury; he had voided urine three or four times, which was not at all bloody. The abdomen shewed no external mark of violence, nor any particular fulness.

Post-mortem examination.—The abdomen was distended with gas and sanguineous fluid. The intestines first seen did not exhibit unnatural changes; but on tracing them throughout, the principal seat of the injury was found to be in the duodenum, just after surrounding the head of the pancreas, in which part a complete separation had taken place where it crosses the second lumbar vertebra. Both apertures were ragged, and of a livid colour; the lower was loose and floating, and portions of digested aliment effused in the abdominal cavity.

On the left side of the spine, where the jejunum commences, was seen a large perforation in the gut, the size of a shilling. There was infiltration of blood between the layers of the mesocolon, and still more so into the cellular membrane around the left kidney; but the kidney itself was uninjured. The peritoneum in front of the kidney, and likewise at the root of the mesentery, was ecchymosed.

The liver was pale; and on the under part of the right lobe, near to the edge, were seen two small lacerated wounds, each half an inch in length. The gall-bladder was entire, containing a small quantity of bile. The other viscera did not appear unnatural.

Remarks.—I am induced to offer an account of this case, as the symptoms herein detailed were less severe, and the sudden collapse much more protracted, than is usually met with where the intestines are ruptured.

MEDICAL JURISPRUDENCE.

ASPHYXIA AND DEATH FROM EXPOSURE TO
THE FUMES OF IGNITED CHARCOAL;*With Remarks on the Presumption of Survivorship.*

BY M. SARDAILLON*.

A LIVELY and healthy child, about seven years of age, went to bed after a light supper of soup. Towards the middle of the night he became disturbed, and uttered some plaintive and convulsed cries. The father, who lay near the head of his bed, got up, but presently found himself overcome with weakness, and fell insensible on the floor. The mother next arose, took the child in her arms, fainted, and sunk on a chair. After a time, how long she could not say, she revived, and found her boy lying on the floor. Affrighted and in the dark, she lost much time in looking for water and vinegar to sprinkle on her husband and child. The father at last recovered his senses; but the boy was dead.

It appeared that the child was in the habit of having, during sleep, convulsive movements of the jaws and upper limbs; often while in bed he used to suffer from impeded respiration, but was immediately relieved by altering his posture into one less horizontal, and by asperision of vinegar and cold water. He had passed worms, and was subject to incontinence of urine.

The body was examined 33 hours after death: its position was easy; no disorder about the clothes, nor mark of cord or ligature. The muscles very stiff; the face colourless and livid; a violet coloured redness of the parts most dependent; a slight excoriation of the left side of the neck, just below the ramus of the jaw; also a little mark of the same kind on the lower part of the chin of same side. The epidermis alone was engaged in these abrasions; there was no mark of ecchymosis or inflammation about them. The mouth was filled with a foamy saliva; the tongue covered with a whitish coat; the mucous membrane of the intestines lined with a thick membraniform layer of pretty tough mucus, beneath which the tissue was found in its full integrity,—the thickness of the

layer becoming gradually less from the stomach towards the great intestine. No trace of lesion about the abdominal viscera. In the chest there was found about a glassful of limpid serum, of rather an amber colour. The pleura costalis of the left side slightly red, from injection of the subjacent capillaries. The substance of the lungs gorged with brilliant red blood; apparently hepatised, yet crepitous through its whole extent. The bronchus and bronchia filled with foamy mucosity; their lining membrane of an uniform violet red colour, the intensity of which diminished sensibly as it was seen near the larynx. The heart very firm in its texture; the right ventricle smaller than usual; the left forming two-thirds of the entire bulk; its parietes seven or eight lines in thickness. The veins everywhere gorged with a semi-liquid blood. The dura mater so closely adherent to the cranium, that the ordinary method of taking off the latter could not be followed. No lesion of the arachnoid. Considerable fulness of the veins and cerebral sinuses with a dark red blood. On slicing the brain a remarkable quantity of blood exuded. No appreciable quantity of serum in the ventricles.

The integrity of the alimentary canal altogether exploded the idea of poisoning, and dispensed with the duty of examining its contents.

But the state of the respiratory apparatus, and of the brain, led us to think that death was produced by a lesion of one or other of these organs. At the same time, from the age of the deceased, and the nature of the changes in the air-passages, we could not help believing that the cerebral congestion was secondary to the disturbance about the lungs, and that the child died of asphyxia rather than apoplexy. The slight excoriations about the neck, however, could not induce us to believe that asphyxia was the result of strangulation; for, besides their slightness, the state of the skin and surrounding parts made us presume that they were inflicted after the death of the child. The deceased, moreover, had fallen from his mother's arms when she fainted, and on her revival was found on the floor near the stove.

The place in which the child and his parents lodged was on a ground floor—a small room not above eight or nine feet square; and it was strongly heated by a stove which was kindled only a

* Bulletin de la Société Médico-Pratique de Paris.

few hours before the accident. There could be no reasonable doubt of the nature of the boy's death; all the circumstances, pathological as well as moral, shewed that the deceased had been asphyxiated by the same cause which operated so violently on the parents also; and from some physiological considerations, we thought we could easily account for the death of the child, while the parents were enabled to recover from the effects of the deleterious influence. The age of the deceased; the hypertrophy noticed in the left ventricle; and the traces of pleurisy which were observable in the chest,—all induced us to this opinion. Then the more robust constitution of the father supplied us also with a reason why the effects of the accident were more strongly marked in him than in his wife; for it has been observed, 1. that the functions of circulation and respiration are carried on more rapidly and vigorously in proportion to the youth of the subject; 2. that in adult age these functions are more active in the male than in the female, in persons who enjoy excellent health than in those who are feeble and delicate; and, on the other hand, both experience and reasoning convince us, that death is not brought on through defect of respiration, but in proportion to the want there is of renewing the air in the chest: all this, supposing the resistance to destructive agents equal. Hence it is that Arts. 721 and 722* of our civil code, touching the presumptions of survivorship, do not appear to us to be well founded in physiology; in cases of asphyxia, particularly, the consideration above stated, and so well developed in part by M. Foderé, ought always to be taken into account, and especially when the differences of age and constitution are so strongly marked.

But how did the stove render the air of the apartment mephitic? Was it the combustion that disengaged carbonic acid and carbonic oxide, by which the

quantity of oxygen in the place was consumed, and life thus rendered incapable of support? This would seem highly probable, were it not for one rather irreconcilable fact. In the present case (the child was dead before it fell from the mother's arms) the father fell on the earth, where, according to chemistry, he should have died, the specific gravity of the gases which we have supposed to be evolved being greater than that of the atmosphere, and therefore necessarily causing them to be more abundantly deposited in the lower strata of the air in the apartment. On the contrary, the man was revived by the coolness of the floor. When the woman Bazin (*Gaz. des Tribunaux*, 9 Août, 1827) was examined about the death of her child, which perished under like circumstances, one of her *naïve* answers to the tribunal was very apropos to what is described to have happened in the present case:—"I fell," said she, "and it was the coolness (*fraicheur*) of the floor that saved me." The coincidence, indeed, in the two cases is so striking, as to send us in search of some explanation which might reconcile the results with what we know from physico-chemical experiments to be at the first view incompatible with them. In the first case, the apartment being immediately adjoining the court, there might probably be kept up a current of air along the floor from without, and the more rapid the more the air of the room was heated. But in the other such a circumstance is less likely, for it was in a back-shop that the transaction occurred; and the woman Bazin had besides taken care to stop up the aperture beneath the door, which might admit the external air.

It might also be thought that the adjustment of the gases, according to their respective specific gravities, had not yet taken place when the catastrophe occurred; but however this might be in the first case, in the second the charcoal was lighted about midnight, and the woman Bazin did not revive till six in the morning.

The animating influence of the contact of a body colder than that which it touches is generally known; the sprinkling of cold water on persons in a state of syncope is indeed one of the most popular of remedies. Might we not discern some distant analogy between the above recited facts, and the consequences of the application of cold in certain syn-

* Art. 721.—Where those who perish together are under 15, the elder shall be presumed to be the survivor; if they be all above 16, the younger shall be accounted the survivor. Where some are under 15, and the rest above 60, the former shall be supposed to have survived.

Art. 722.—Where those who perish together are between 15 and 60, the male is presumed to have survived, when the difference of age of the parties is not above one year. Where the parties are of the same sex, the presumption of survivorship in the order of nature ought to be admitted; thus the younger shall be presumed to have survived the elder.

copes? It would still, no doubt, remain to account for the difference or analogy of the state of the nervous system in the several circumstances, and to demonstrate the theory of the action of cold in different conditions of the body. This, however, it must be admitted, we are but ill qualified to do in any thing like a satisfactory manner, in the present state of our physical knowledge.

AN EXTRAORDINARY DILATATION (WITH
HYPERTROPHY?)

OF THE

THORACIC PORTION OF THE
ŒSOPHAGUS,

Causing Dysphagia.

NARRATED BY ALEX. J. HANNAY, M.D.

J. L. æt. 38, rather short of stature, was, however, well proportioned, muscular, and of active habits. On taking food he experienced a sensation as if it were arrested in the œsophagus, a little way above the lower end of the sternum, giving rise to the most painful and protracted efforts to swallow. Early in the history of his case, there was merely a sense of uneasiness in the epigastric region created by taking food. This gradually became more distressing, and at a late period occasionally amounted to an agonizing sense of distention. This suffering was worst after a full meal, and generally subsided slowly; hours used to elapse before it was completely gone. The nature of the food or ingesta did not modify the complaint in any observable degree, yet a large quantity always increased the evils of his condition. Immediate relief could be obtained by vomiting, which he was often induced to excite to remove his distress. After intemperate indulgence in spirits, to which he was much addicted for a considerable time previous to his death, the pain on taking food was aggravated, and the vomiting came on spontaneously. Under these circumstances, fluids alone, for example tea in the morning, gave rise to the agonizing feelings above described; though when temperate, he only felt slight uneasiness from taking ingesta of this nature. No obstruction was experienced on passing a probang. The sounds of the chest on percussion and auscultation were natural.

The difficulty of swallowing had existed since boyhood, at which time he received a violent blow on the chest, inflicted by a club or shinty; it has left no external marks. Since that accident he has had more or less uneasiness in the epigastric region, and impeded ingestion; but his memory failed him in describing the circumstances which attended the injury, and his account of the case at that time was most meagre and unsatisfactory. It has gradually become more urgent with advancing life, and has always been modified and aggravated by the circumstances before mentioned. His general health did not appear to suffer much from the dysphagia, and any changes which his constitution and aspect experienced were rather attributed to his intemperance than to the difficult deglutition. He had of late complained of a constant sense of oppression in the chest, made worse by running up stairs, or by violent exertion.

One morning, about half-past three o'clock, he walked home from a supper party, after eating most heartily, and drinking as usual to excess. He did not go to bed, but, as was his custom when tipsy, sat down on a chair and fell asleep, with his head in a position calculated to prevent the free return of the blood from the head. His friends have frequently seen him sleeping in this position till his face became livid.

He had fallen forwards on his face and on his knees, as if kneeling, and the wall against which his side fell supported him till found in this attitude.

No one can give any account of his last symptoms, for he was found quite dead between five and six o'clock: say two hours, or two hours and a half, after he had walked up stairs by himself.

Dissection 32 hours after death.—On turning the right lung to the left side of the chest, in order to cut it out, I uncovered and displayed a long sac, running on, and parallel to the spine, covering that column and projecting over it into the right side of the chest. It was distended by fluid; the distention was increased by pressing the stomach, and pressure on the sac forced back the fluid into the last-named viscus. Until I observed this, I imagined that the appearances arose from an aneurism having burst into the posterior mediastinum, a circumstance that well agreed with the sudden death of the individual; but the above communica-

tion, and a little more investigation, immediately shewed that the sac in the mediastinum was the œsophagus enormously dilated and distended with ingesta.

The dilatation began immediately on its entrance into the chest. The cervical portion was perfectly natural. It gradually grew wider till it reached the middle of its course in the thorax. There the sac measured, as it laid collapsed on the table and unopened, rather more than three inches across, or when fully distended with fluid, more than six inches in circumference. The thoracic portion alone required above eight gills of water to fill it; and when so filled, it looked like the arm of a person fifteen or sixteen years of age. From the middle of the thoracic portion it gradually diminished in capacity till it reached its appropriate aperture in the diaphragm, where it was of its natural dimension.

I found in the œsophagus a very considerable quantity, about a pint (English) of a light-coloured fluid, something like white or pea-soup (but approaching to a buff colour), consisting, besides the liquids, of particles of fowl, ham, and bread, which appeared to have been in the stomach, and to have undergone a partial digestion.

The parietes of the tube were several times their ordinary thickness, and, comparatively speaking, dense and strong; they had lost almost all trace of muscular texture; the appearance of a section of them reminded me of a piece of sole or thick leather; they had a good deal of blood in them, and seemed very vascular. Its internal or mucous coat was very vascular, arborescent, and red; it was as it were spotted with abrasions of its cuticle, and felt rough and scabrous to the finger. Some parts were smooth, and being less red, appeared almost natural. There was no obstruction either by tumor external to, or by constriction within the canal. The aperture by which it penetrated the diaphragm was quite patent, of the natural size, and presented no obstacle, nor could any be detected on minutest examination.

There were no remarkable appearances in any other organs, though carefully examined.

I do not regard the morbid condition of the œsophagus as causing this man's death; for a more harmless organic cause of dysphagia can scarcely be imagined. Here there was

no likelihood of the nourishment of the body failing, a circumstance which, in the usual morbid states preventing ingestion of food, is one of its most distressing symptoms, and often the reason of its proving fatal. Marasmus and a cachectic aspect usually appear in even some of the slighter degrees of this dysœsœsia, and certainly in all presenting such difficulty in the act of swallowing as the case before us exhibited. Many of the cases of this nature are dependent on specific morbid actions, as carcinoma, or on morbid conditions of the neighbouring parts, as aneurisms, tumors, &c. which injure the general health, or otherwise materially impair the vigour of the body. Many, indeed, perish before the passage is completely obstructed.

In the case before us, the food, though it often excited distressing sensations in its passage, did reach the stomach, and the functions of that organ continuing unimpaired, it sufficiently nourished the body.

Here is a striking peculiarity in the circumstance of the unimpaired vigour and health of the system during nearly thirty years of dysphagia, long presenting as great severity of symptoms as any fatal case I ever witnessed: and may I adduce as another peculiarity the fact, that a probang passed into the stomach as freely as possible, even when his impeded deglutition was most distressing?—a circumstance for which the post-mortem inspection fully accounted. This pathological fact shows what is, however well established by other observations, the important part performed by the œsophagus in deglutition. We are not then to attribute death to dysphagia, or the morbid condition of the œsophagus.

The appearances in the œsophagus impressed me with the idea of inflammatory action having been the process by which this morbid change had been accomplished in that organ. The highly vascular, red, and swollen state of the walls or layers of which the tube was formed, were in accordance with this view. The aggravation of the symptoms by a course of life, or practices calculated to increase inflammatory disease, admits of a similar solution. The irritated and abraded surface pronounced inflammation to be in operation in that texture. The painful sensations denoted increased sensibility, and the existence of inflammatory disease in the part.

The increased thickness or hypertrophy of the walls of the tube likewise denoted increased action, and the total subversion of its natural structure; and the substitution of one of a new character accorded well with the phenomena of chronic inflammation in many other textures—a process which Mr. Abernethy quaintly, and not inaptly, defined to be the destroyer of old or original textures, and the builder of new ones in their stead.

Repeated attacks of inflammation of the Œsophagus had probably destroyed its muscular structure and its contractile power. Swallowing was impaired; the food was detained and accumulated; and the distention by the ingesta had by degrees mechanically dilated the canal.

(In the *Med. Obs. and Inq.* vol. iii. p. 85.) there is on record a case in which the pharynx was partially dilated by a mechanical cause, accompanied by obstinate and fatal dysphagia. A cherry-stone accidentally lodged in a fold of the pharynx of a man somewhat advanced in years. It remained three days, exciting much pain on swallowing, and was ejected by a violent fit of coughing. The painful sensations in the part soon subsided, and the accident had well nigh been forgotten, when about a year thereafter, portions of the patient's food began to be thrown up into the mouth, having undergone no change, and without any sickness. At first, the aliment remained down for some time, and the quantity returned was but small. Gradually the quantity increased, and the time became shorter. At length the regurgitation took place immediately on swallowing, particularly fluids, and occasioned a sense of urgent strangulation. Complete obstruction to the passage finally ensued; no nourishment could be taken; no instrument could be passed; and the patient died in thirteen days, during which time nutritious fluids were diligently injected per anum.

Dissection showed that the pharynx had become sacculated—that the sac or pouch, projecting from its posterior aspect, passed down between the Œsophagus and the vertebræ, and pressed this tube so strongly against the larynx and trachea, as to render it impervious. Its magnitude was increased by the distention of food or drink taken into it, and the cause of the difficulty of swallowing

thus clearly explained. The probable conjecture is, that the cherry-stone first distended the pharynx, and that lodgment of food had gradually increased the partial distention, and augmented its capacity. The weight of the sac and of its contents dragged the mouth of the sac into that position most favourable to the interception of any article passing downwards, and presenting a ready admission to the instrument of the surgeon seeking the natural passage, which was by the stretching or dragging drawn out of the straight course. I notice this case not only from its curious character, but as illustrating the view I take of the dilatation in my case having been in part at least induced mechanically. The Œsophagus having lost its muscular power, lost also its power of contraction; the food was consequently retarded and accumulated in the canal, causing the distention to which its sides had yielded; otherwise, there is no analogy between the cases. The dilatation was merely partial in the case I abridge from the *Medical Observations and Inquiries*. In that I record it was universal along the course of the tube, from the clavicle to its passage through the diaphragm. The Œsophagus in the former case was little if at all altered, except in the situation of the sac, by any morbid condition of its texture. In my case it was hypertrophied to a very remarkable degree, and the mechanism productive of the difficulty of deglutition must have been very different in the two instances.

Morgagni (*Epist.* 28, p. 18,) enumerates dilatation of the Œsophagus amongst the morbid states of that organ giving rise to dysphagia.

He does not appear to have met an instance of this pathological state, but refers to one recorded by Joannes Græhns, which appears to be analogous to the case produced by the cherry-stone:—“*Nempe Œsophagi circa medium thoracis morbosam in saccum lateralem dilatationem, aquâ subinde variantia symptomata quæ nunquam sine dissectione intelligi potuissent.*”—*Act. N. C. T. C.* Obs. 73.) This is only a partial dilatation, and no mention is made of the condition of the structure of the Œsophagus.

The Œsophagus is capable of great elongation also by a stretching power, as a case narrated by Dr. White, of Manchester, by the dragging of a prolapsus uteri, the Œsophagus being greatly

lengthened, allowed the stomach to descend into the umbilical region.—*Med. Obs. and Inq.* vol. iii. p. 3.

The case which approximates most closely in some particulars, though not by any means in all, is one given by Portal.—(*Anatom. Méd.* tom. v. p. 204.) The œsophagus had become thickened in its parietes, and greater in capacity than the stomach. But there was a very obvious cause. The orifice of the cardia was contracted to such a degree as scarcely to admit a large writing pen: its circumference was swollen, hardened, and unequally embossed (*bossellé*.) M. Portal had no account of, or what is to us nearly the same thing, he has not favoured us with the symptoms during life—a circumstance which materially diminishes the interest of his observations*.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Observations on Injuries and Diseases of the Rectum. By HERBERT MAYO, F.R.S. Surgeon to the Middlesex Hospital.

MR. MAYO informs us that he has been led to write upon the subject of the present volume “by several considerations.” Some of these he states, namely, the frequency of diseases of the rectum; their inconvenience, and the pain they occasion; the extent to which they admit of relief when judiciously treated; and their aggravation when treated unskillfully. The author may have other motives, but those put forth are sufficiently plausible, and such as would justify a surgeon of less intelligence, and more limited opportunities, in laying the results of his experience before the public, on any important disease. The rectum is evidently a very favourite subject, and every year we find some fresh “Observations” on our table; so that no blame can attach to the labourers in this branch of surgery if it be not well understood. Many of these works, however, are mere catch-pennies, written more for the public than the profession—half-popular, half-

medical—“springes to catch woodcocks,”—traps for patients; and we believe, upon the whole, they work tolerably well. Mr. Mayo's *Observations*, however, will be read with more interest than the works alluded to; for though not perhaps containing much that is absolutely new, they are yet judicious and practical, and the descriptions are elucidated by little wood-cuts, which tend to render the subject more clear and intelligible. The maladies discussed are fissure and laceration of the rectum; protrusion of the bowel; hæmorrhage and pain about the anus; piles; fistula; constipation, and the use of instruments; stricture of the rectum; and cancer.

The chapter on constipation is interesting, and contains some good practical remarks: we shall therefore select it for analysis in the present number, as affording a fair specimen of the volume. Mr. Mayo observes, that the disorders he has previously treated of, viz. hæmorrhoids, fissure of the rectum, fistula ani, &c. might be classed together, though somewhat loosely, as the results of constipation; while those which follow, including mechanical obstructions about the lower bowel, carcinoma, &c. might be looked upon as having this in common, that they lead to constipation as a frequent consequence. In a sort of transition chapter, therefore, he discusses the causes of constipation of the lower bowels, and the precautions necessary in the use of instruments.

Obstruction of the bowels he regards as dependent upon one of three causes; either lack of the secretions necessary to the formation of feces; or the want of the fluidity required for their expulsion; or the absence of sufficiently stimulating properties; or, lastly, the enfeebled state of the muscular fibres of the bowel. Other theoretical explanations might be adduced, but the author contents himself with the above, and gives some examples in illustration.

Of the cases thus narrated, the following is one of the most interesting, and is certainly a very striking instance of the effects which occasionally present themselves in connexion with, if not entirely dependent upon, constipation.

“I was requested to see a young medical man, who I heard was in a fit. I found him lying on the floor, sensible, but exhausted with suffering; the flexor muscles of the limbs, and the muscles of

* Condensed from *Edinb. Med. and Surg. Journ.* for July.

the abdomen, were in strong spasmodic action. He had been in this state for several hours. Ammonia and hot brandy and water were given him, and he gradually rallied. This I learnt was not the first seizure of the kind which he had experienced. Attacks of a similar description, but of less severity, would come on several times in the year; they were preceded by obstinate costiveness.

"This patient, now 28 years of age, up to the age of 15 enjoyed excellent health. At that age his bowels fell into the state of costiveness which has continued since. He grew up of a slight and delicate frame, physically incapable of much bodily exertion, and indisposed to it by a languor and drowsiness, which probably arose from the imperfect action of the bowels. The bowels now act once in five or six days only; what is then passed is healthy; it is only extraordinarily deficient in quantity. With this he has little appetite; and even that he is afraid of indulging, lest it should lead to one of the attacks which I have described. These attacks, it has been mentioned, recur, when the bowels have been confined for an unusually long period. The belly then becomes hard, and a little swollen; there is sickness, but nothing is thrown up but what has been recently taken into the stomach; there is a sense of uneasiness and pain above the umbilicus. When at the close of such an attack the bowels are relieved, the motions which pass are still extremely scanty.

"When I was asked to see this patient, it was under an impression that he possibly laboured under stricture of the colon. It is not the only instance in which I have seen deficient formation of feces mistaken for their retention. But it was needless in this case to look for a cause of obstruction, when there was no evidence that an accumulation of feces ever took place. At the close of the severest seizures, the hardness and tension of the belly went away upon the expulsion of a quantity of feces not equalling the ordinary daily excretions of a healthy person. This patient has taken every medicine, and every combination of medicines, not entirely without advantage, but without finding that he can calculate upon obtaining relief from the same remedy a second time."

Mr. Mayo alludes to the idea of Dr. O'Beirne, that the rectum does not in its

healthy and natural state contain feces, and remarks in refutation of his doctrine, that in post-mortem examinations, as well as in the living body, feces are as often found in the rectum, and in the higher parts of the colon, as in its sigmoid flexure; the last being the reservoir *par excellence* of Dr. O'Beirne. With respect to the passage of a tube high up into the bowel, founded on the hypothesis alluded to, he remarks that it is not so perfectly free from danger in inexperienced hands as to warrant its general recommendation.

The deficiency of stimulating property sufficient to excite the bowel to due contraction, is seen in imperfect biliary secretion. In some of these instances the torpor leads to great accumulations, especially about the rectum, and when within the reach of instruments, these collections may generally be removed by their means; but sometimes they are too high up for this, and the cure must then be trusted mainly to the more powerful purgatives. In cases, however, where the secretion is deficient, or the muscular action imperfect, it may still be asked on what these are themselves dependent? The following case is intended as an answer to the inquiry:—

"I was consulted in the case of a young lady, one of whose symptoms was obstinate constipation of the bowels, requiring that she should take nightly from twenty to thirty grains of compound extract of colocynth, to produce an action of the bowels the following day. She had been ill four years, and her sufferings had commenced with severe pain across the belly, and obstinate costiveness. After a fortnight's illness the constipation yielded; but one leg became feeble, and the knee of that side was frequently spasmodically bent. This complication of palsy and spasm soon after affected the opposite leg; afterwards one hand became feeble and contracted. These symptoms grew upon her; but she retained a remarkably fine complexion, and had the appearance, when making no exertion, of perfect health. I entertained little doubt that all the symptoms in this case originated in an affection of the spinal marrow. The vertebral column was indeed perfectly straight and even; but the patient often experienced pain at the lower part of the dorsal portion, and pressure there gave her uneasiness. I recommended that issues should be made at

the lower part of the back. The remedy was followed by great relief of all her symptoms. The legs seemed less weak, the knees were not so frequently or so painfully contracted, and the bowels acted with half the usual dose of drastic purgatives. This improvement, however, was temporary only; and, disappointed of obtaining permanent relief, this patient consulted other surgeons, as she had consulted several before she applied to myself. She died six months afterwards; and, on examining the spinal cord, it was found for the length of two inches in a state of softening at its lumbar portion.

"This is one of a numerous class of cases in which constipation of the bowels is found to depend upon spinal irritation, and in which the abdominal symptoms are the first which shew themselves after the invasion of the disease. The re-action of the one organ upon the other is very remarkable.

"An amendment of the state of the bowels is an evidence of a temporary alleviation of the spinal disease. The neglect of relieving the bowels by medicine is followed by an aggravation of the nervous symptoms."

Some observations are next made upon the other circumstances which influence the action of the bowels, such as habit, exercise, &c. &c.; but as these contain nothing very important, we pass on to the account given of the use of instruments. As it is notorious that a prodigious degree of quackery is daily practised on this point, we shall extract at length Mr. Mayo's opinions on the subject:—

"The instruments that are required under different circumstances to be introduced into the rectum, are the wax bougie, the flexible tube, and the tube of the injecting syringe.

"A good wax bougie should admit of being rendered perfectly pliant and flexible by immersion in hot water. Except in this state, a bougie cannot be introduced with safety beyond four inches into the rectum. Even when it has been rendered pliant, a bougie introduced into the intestine generally meets with some degree of obstruction after passing from five to six inches. The nature of this obstruction is readily shewn by anatomical inspection. The end of the instrument catches against the lax walls of the rectum, and pushes before it the substance of the gut as a

blind sac. Under these circumstances, if force is used, the instrument tears the intestine, and passes into the cavity of the belly.

"No adroitness can prevent the rectum being thus caught up in sacs by the bougie; but some nicety of observation is required to distinguish the yielding resistance which such a sac offers, from the resistance of a stricture. It is very certain that surgeons are occasionally thus misled, and assure their patients that they have stricture when there is none.

"When the resistance is a sac of intestine that the instrument has temporarily produced, it will follow that if the instrument is drawn back a little, and then again passed forward with the direction slightly altered, it will keep the channel of the intestine, and not sacculate it at the same place as before. I met with a case some years ago, in which the symptoms led me to think that there was stricture in the sigmoid flexure of the colon. To ascertain the point, I passed a bougie three feet in length into the bowel; the bougie was something more than half an inch in diameter. It continually caught in the manner which I have described; but by withdrawing it slightly when this happened, and again pressing it gently on, I succeeded in introducing the instrument its entire length, with very little inconvenience to the patient.

"A bougie from half an inch to three quarters of an inch in diameter is quite large enough for the examination of the rectum. If such an instrument pass easily and without pain along the bowel, it may be safely presumed that there is no contraction.

"Before introducing a bougie, a double bend should be given to it, one corresponding with the curvature of the sacrum, the second with the inclination of the sigmoid flexure of the colon to the left. The surgeon should, however, bear in mind, in reference to this second point, that the bowel occasionally inclines to the right side instead of to the left; and if he meet with any ambiguous resistance, he should, by withdrawing the instrument a little, and again passing it forward with an altered direction, endeavour to find the natural course of the gut.

"I have described the method by which instruments may be safely introduced a considerable height into the

bowel; but it will be seen from the remarks which follow, that it is rarely necessary to pass instruments a greater distance than four or five inches.

"In the introduction of the flexible tube, the same precautions are to be used as in the introduction of the wax bougie. Its elasticity renders this instrument perhaps more liable to catch up the bowel than even the bougie. The tube should terminate in a smooth round end, with two large apertures at its sides. The great point which cannot be too strongly impressed upon the mind of the practitioner, is the extreme delicacy of the part, and the readiness with which it will tear under very moderate pressure.

"The tube which forms the extremity of the ordinary injecting syringe is generally too long and too narrow. The part introduced into the bowel should not be more than an inch and a half in length, and the extremity should be a portion of a sphere, exceeding half an inch in diameter. I have already mentioned cases in which the rectum was torn by the common injecting syringe. Mr. Stanley very recently showed me another example of this accident. A female had died suddenly from inward hæmorrhage, owing to the rupture of one of the fallopian tubes. She had not laboured under disease of the rectum; but a lavement had been administered. The mucous coat of the intestine, which was looked at in the examination, was found raised and torn for a short extent, at a little distance within the sphincter, evidently from violence done by the tube of the injecting syringe.

But it is not only immediate laceration and rupture of the bowel which is to be apprehended from the incautious use of instruments. There is every reason to believe that mechanical hurts occasionally give rise to malignant disease of the rectum, and that roughness and want of care in the employment of instruments are capable of producing cancer in this part."

In referring to the volume itself for farther details, we shall conclude by observing, that though we cannot agree in all points with Mr. Mayo, yet we think that his "Observations" are for the most part instructive; and that they are entitled to a higher character than can with any candour be given to most of the recent works on the same subject.

Since the above was written, we have

seen in the newspapers and journals an advertisement of Mr. Mayo's "Observations." We very seldom allude to such matters, but the manner in which the work is introduced to notice is so entirely unprofessional, as to be calculated to undo what we have said in its favour, and to place it in the class of publications from which we have been anxious to rescue it. This specimen of the "puff direct" we of course attribute to the injudicious zeal of the publishers; but if suffered to be repeated, the world—at least the medical world—will be ill-natured enough to believe that it is done with the connivance of the author.

MEDICAL GAZETTE.

Saturday, September 7, 1833.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

PARLIAMENT AND THE PROFESSION.

OUT of one hundred and thirty-four notices of motions which are on the books of the Commons' House of Parliament as matter of business for the next session, we find but a solitary single one that has any reference to medical affairs: it is Mr. Warburton's motion (standing No. 20 on the list) for a "Committee to inquire into the laws and regulations affecting the education and practice of the members of the medical and surgical profession in the three kingdoms."

In our observations last week we noticed the attention which parliament had latterly paid to matters of medical polity, and we thought we had reason to congratulate the profession on the degree of interest which appears to be publicly excited by the same subject. We think so still: but there are a few points on which it will in a great measure depend, whether or not that attention, and that interest, be ultimately productive of any good to them most nearly concerned.

The fact which we have just mentioned of the *share* of attention which parliament (or we should rather say a single member) stands pledged to give to medical affairs in the ensuing session, ought, we conceive, to operate strongly in repressing hopes of relief from the unstimulated exertions of our legislators; and the experience of former proceedings of the House relative to the adoption of measures long and anxiously called for—the Anatomy Act for example—ought to have some little effect in restraining a false confidence that the reform so generally desired in the profession will be a matter of speedy adjustment. Nothing is more clear than that if things be allowed to take their own formal course, session after session will pass away and leave no memorial of legislative wisdom to enlighten and regulate our successors: nor is there any inference more obvious than that if success in the carrying into effect the arrangements proposed be at all desirable, there must be no relaxation in the efforts of the friends of those arrangements, nor a moment lost in idly expecting that result whose alpha and omega rest mainly on the energy of its promoters.

That parliament will ever carry a measure for the relief of any body of individuals, however large and respectable, without the special and active interference of such body, is not to be expected: but the history of last session will serve to show, on the other hand, how far the collective wisdom may be influenced by the bustling energy of parties, however small and otherwise contemptible, just from the very circumstance of permitting itself to be bored and tired out by the importunity of the interested. The intriguing with which the Factories' Bill (in the shape adopted by Lord Althorp,) the Irish Infirmarys' and Grand Juries' Bills, and certain other jobbing measures, have been inoculated into the law of the land, ought, along with the late Lottery Bill,

to afford an ever-memorable example to the dishonest of the utility of intriguing when they have an object to effect; while neither need the honest decline to profit by the lesson, inasmuch as it shows them how perseverance and the unremitting efforts of any party, will have their due weight in legislative quarters. How narrow was the escape from the enacting of the Scotch Apothecaries' Bill, and all the mischievous consequences which it would have inevitably entailed; and this simply from the prompt management of the agents about that Bill, feebly, but yet as luck would have it, effectually opposed by the large body of persons in this part of the realm whose interests, and very means of life, were at stake! On the other hand it will occur to most of our readers how weary and tedious were the proceedings which terminated in the adoption of the Anatomy Bill. Year after year rolled by; petition on petition from practitioners and teachers in all parts of the United Kingdom, was piled on the table of the House; inquiries were instituted by authority both in and out of parliament; and a committee, one of the most pains-taking and inquisitive usually to be met with within the walls of St. Stephen's, sat for a long time on the matter, and heard all the ablest evidence that could be procured from every quarter; yet the Bill framed upon the results of these varied inquiries was lost after all in the Upper House, through the defective information under which some of the highest authorities in the land laboured; and it was not till four or five years later that the present Act—a merely permissive measure—was reluctantly suffered to pass. These are signs of the temper and feeling which are abroad respecting the concerns of the profession; signs which the wise and prudent will not have considered in vain.

If facts such as these do not speak for themselves, what hope can there be that words will make them more intelligible?

If such pains as those just mentioned were requisite for the enactment of a plain, simple, straight-forward measure, like the Anatomy Act—the only measure, by the way, which parliament has condescended for many a year to take cognizance of, for the better regulation of the profession—and if intrigue can do so much in influential quarters, in the way of thwarting good designs and forwarding evil ones—it scarcely requires a soothsayer to apprise the ordinarily wise and prudent how much it behoves them, in endeavouring to carry into effect a matter so complicated and so unpopular as medical reform, to devote all the energy they can spare to the grand object of accomplishing their purpose.

When we say that the question of medical reform is unpopular, we speak generally. The whole business of medical polity is unpopular, for it is complicated, and not generally understood; and when the work of reform, which has cost the nation of late so much anxiety, and raised such turmoil in its application to the wants of the people at large, is now proposed to be extended to a particular portion of the population of the realm, however important that portion may be, the comparatively minor details and minutiae of their proposed arrangements come over the senses of the mass of the community with little less than the relish of a *crème brûlée*: it is indeed “caviare to the general.” Can there be a stronger proof of this than that which is afforded in the programme of the performances for the next session of parliament? Honourable members, themselves not overburthened with zeal for the welfare of the faculty, know how the wind blows regarding the sentiments of their constituents; and while they propose to legislate for the bettering of “things in general,” they will have as little as possible to do with the particular affair of meddling with the profession. However, they have a shrewd guess as to what is suited *ad captandam*, and what is not; and accordingly, of the

134 magnificent designs with which they propose to themselves to entertain the public at their next meeting, we are gratified to find that a committee of inquiry into medical affairs, is one.

But, seriously speaking, the moral of all these several considerations ought not to be thrown away. In carrying the project of medical reform, the co-operation of large masses, as in that which concerned the nation at large, is not to be expected; nor can much dependence be placed in the *leadership* of individuals. Select, discreet, and energetic, though not numerous parties, will be found to be the most efficient. The main object must be well understood and steadily kept in view; the reformers of the profession must be agreed as to the end which they propose, and they must be unanimous in the steps which they take to attain it. With these few simple maxims, and a resolute determination to despise the ravings of the destructives, who neither know whence they came, whither they go, nor what they would be at, we would venture to predict for our steady reformers the event which they and we most ardently wish—namely, a wholesome but not exterminating reform.

DECREASE OF CHOLERA.

THE cholera, which, as we stated last week, had visibly begun to decline, has undergone a more unequivocal diminution within the last six or eight days than during any former period since the commencement of its present irruption. We are glad to find by the Bills of Mortality that the deaths from cholera have diminished to 69 in the week, the number a fortnight ago having been nearly 200. In fact, the late sudden reduction of temperature, and the change in the atmosphere effected by the late heavy gales, seem to have had a beneficial influence on the epidemic. If this improvement should continue, the preservation of life on shore may be set against the melancholy losses at sea, and the old adage still remain true—that “it is an ill wind that blows nobody good.”

THE LATE DR. DARWALL.

—

WE had lately the painful task of announcing the death of Dr. Darwall, of Birmingham, but under circumstances which prevented us from being able to do any justice to his memory. We have therefore condensed some observations on his character from the *Warwick Advertiser*, and we hope that the "friendly biographer, to embalm his memory," will be found in the accomplished physician from whose pen it is easy to perceive the following effusion has emanated.

The death of this eminent and respected physician, which took place on the 10th ultimo, was occasioned by an injury received in the examination of a dead body, at the Birmingham Hospital, on Tuesday, the 30th of July. During that day, Dr. Darwall was unsuspecting of having incurred any danger. He pursued his usual avocations, visited his patients, and in the evening walked in the Botanic Garden. Very early in the morning of Wednesday he was attacked with severe shivering, to which violent re-action soon succeeded, with inflammation of the absorbents of his left hand and arm. Although these symptoms subsided, under the skillful attentions of the professional friends who were soon assembled round him, his system never recovered the shock; and after eleven anxious days, during most of which sanguine hopes were entertained of his recovery, he breathed his last. Dr. Darwall has been suddenly snatched away, in the prime of life, from his family, from his friends, from the midst of labours only suspended by the illness of a few days—labours such as few could have sustained, and from the performance of duties, the termination of which, before he had attained his 40th year, will long be felt as a calamity by numerous patients of all classes. The shortness of his last illness—its accidental origin—and the abrupt cessation of his extraordinary mental activity—are circumstances so painfully afflicting to his family and to his immediate friends, that even the very general concern which has been occasioned by these sad events cannot, for the present, be expected to soften the poignancy of their sorrow. If great mental acuteness—if extensive learning—if a profound

knowledge of medicine, united with the highest practical skill—if industry the most indefatigable, and benevolence no less enlightened than it was ardent, could have been any protection from an early death, the public might yet, for many years, have benefited by his ability and his experience. After several years of honourable toil, and no small portion of the anxieties experienced by physicians in the early part of their practice, Dr. Darwall's professional engagements had for some time been greatly increasing; and of no member of the medical profession in this county might it have been more confidently predicted, that he would eventually enjoy the most extensive fame, and realize an ample fortune.

For about two years before his death, he held the office of physician to the General Hospital—long an object of his ambition, and to which he was elected by the governors with the most flattering marks of consideration; individuals of all parties concurring in the appointment, and more than one of his medical competitors succeeding from all opposition to claims which rested on every merit that could entitle a medical practitioner to distinction. One of his first steps, after his appointment, was to commence a series of lectures on such cases as he deemed the most instructive; from which, if his life had been prolonged, the pupils of the hospital would doubtless have derived great advantage.

His work on the Diseases of Children, published about three years since, is characterised by all that should distinguish the production of a practical physician; and the remarks on Spinal Irritation, appended to it, excited very general attention from the profession. He had proceeded some way in a History of Medicine, the first part of which is, we believe, about to be published under the superintendence of the "Society for the Promotion of Useful Knowledge." His contributions to the *Cyclopædia of Practical Medicine*, on the Diseases of Artizans, and on the different varieties of Dropsy, possess the highest value. He was engaged in the preparation of some papers on the Curability of Consumption, intended for the Transactions of the "Provincial Medical and Surgical Association;" which, as they would have been (like all his writings) the result of long observation and sound judgment, it is to be hoped may be found sufficiently advanced for publication.

At the late great meeting of medical men, held at Bristol, he was unanimously appointed to deliver the Oration at the next anniversary of the Association, to be held at Birmingham, in July 1834. Death has abruptly ended all his undertakings; but justice will, we trust, be done to those of which his too short life had permitted the completion, and some friendly biographer be found to embalm his valuable memory; for his accomplishments, his intentions, and all the excellent qualities of his heart, were only thoroughly known by those to whom a long intimacy had unfolded them. We know that we are justified in saying that such was the well-founded opinion entertained by his medical brethren, of his practical ability and of his spotless integrity, that, although he neither possessed the softness of address which wins at first sight, nor any of the weakness which conciliates by injudicious concessions, he was becoming every day more and more resorted to by those who either wished for the consolation of his attendance, or the guidance of his almost unerring professional judgment. His habits, and the whole character of his mind, were such as to render him fully and entirely deserving of such confidence. It might be said of him, that his very nature forbade him to be indolent. He was never weary of mental labour. His reading was most extensive and various; and whilst his acquaintance with his own profession knew no limits but that of medical science itself, there was no department or kind of literature, ancient or modern, of which he could be said to be entirely ignorant; and with all the best and too much neglected literature of the English language he was most familiar. None of the vulgar methods of destroying time were necessary to him—he required none of the common relaxations, and was attached to none of the common amusements of life. Practical observation, active duties, reading and reflection, filled up every hour.

The suspension of a career so patiently and diligently pursued, just when the early difficulties with which he had manfully contended were nearly overcome, and every prospect was at length opening more widely and brightly, cannot but be felt by his relatives and his friends as an affliction of the severest kind. Whilst the medical profession has

lost a physician whose attainments and whose character reflected honour upon medicine, society has lost an invaluable member.

ROYAL COLLEGE OF SURGEONS IN LONDON.

To the Editor of the Medical Gazette.

SIR,

I AM directed by the President to transmit to you the enclosed copy of a Statement, &c.; and am, sir,

Your obedient servant,

EDM. BELFOUR, Sec.

College of Surgeons,
4th Sept. 1833.

IN pursuance of a Resolution of the Council, on the 29th of January last,

“That an exposition of the state of the College be from time to time made to its members,”

The Council publish the following

STATEMENT.

The Corporation of Surgeons, established as a distinct body, by Act of Parliament, in the year 1745, having become dissolved in consequence of an accidental informality in their proceedings, the present Royal College of Surgeons was founded in the year 1800 by his Majesty King George the Third, for the advancement of surgery, for the examination of surgeons in the army and navy, and of other individuals who might wish to engage in the surgical profession.

The repute in which the Corporation was held appears to have been so limited, that a large proportion of the practitioners throughout the kingdom had undergone no examination, and had not even a nominal connexion with it. The inheritance derived by the College from the Corporation was as follows:—10,135*l.* 7*s.* 5*d.* 3 per cent. Consols; 1233*l.* 15*s.* 0*d.* due from the City of London for the Hall in the Old Bailey; 2862*l.* 16*s.* 7*d.* in Exchequer Bills and at the Bankers; the house in Lincoln's-inn Fields, which then occupied one-half of the site of the present premises; and a rent-charge of 16*l.* per annum on premises in Snowhill, bequeathed by Mr. Gale for the endowment of a Professorship of Anatomy. There were no certain funds of any other description, for defraying the expense of maintaining the great national collection purchased by Parliament of the executors of Mr. John Hunter, and which

the College now holds in trust for the public.

When the College received its Charter from the Crown, it derived no assistance of any kind from the other branches of the legislature: the Charter was simply permissive, allowing the Court of Examiners to examine those who might voluntarily present themselves, but giving them no legal authority whatever to compel practitioners in surgery to obtain their diploma, nor to prosecute those who took upon themselves to practise without it. The College, therefore, possessing no other influence than that of opinion, was left to rest altogether on its own character. Under these circumstances, it would never have advanced to its present state of prosperity, if it had failed to obtain the confidence of the profession and the public; and the best proof that it has succeeded in this object is to be found in the increased and increasing number of the members. In the first two years after the establishment of the College, the diploma was granted to 300, and in the last two years to not fewer than 770 members.

Although the College derives an important accession to its scientific character, from the possession of the Hunterian Collection, its preservation and public uses have been a source of great expense to the institution.

The sum of 27,500*l.* obtained from Parliament having been insufficient for building the Museum, an addition, amounting to nearly as much, was supplied from the funds of the College. But independently of what has been laid out on the building of the Museum, about 36,000*l.* have been expended on its contents. The Council have always regarded the charge of the Collection as one of the most important trusts of the College; and they believe they have best performed their duty by sparing no expense which might tend to make it as complete as possible.

Thirty Lectures are delivered annually in the Theatre of the College, by two Professors appointed by the Council. To these the members of the College are admitted by right, and the senior students of the metropolitan hospitals by courtesy.

The Library, collected within the last six years, and comprising the most valuable works in medicine and surgery, as well as in general science, is open to the members of the profession and other scientific persons, on the most liberal conditions.

Notwithstanding the large demands made upon the funds of the College by the maintenance of the Collection, by the formation of the Library, and by the management of the general business of the institution, the annual expenditure has hitherto

been kept within the limits of its income, so that a considerable funded property has gradually accumulated, which is now at the disposal of the Council, to be applied, as opportunities may occur, for the advancement of the sciences connected with surgery.

The following are more detailed statements, relating to the Museum, Library, and Finances of the College.

MUSEUM.

The valuable Collection of Preparations made by the late John Hunter, was entrusted to the Corporation of Surgeons, on the following conditions:—

- “ 1st. The Collection shall be open four hours in the forenoon two days every week, for inspection and consultation of the Fellows of the College of Physicians, the Members of the Company of Surgeons, and persons properly introduced by them; a Catalogue of the preparations, and a proper person to explain it, being at those times always in the room.
- “ 2d. That one course of Lectures, not less than twenty-four in number, on comparative anatomy and other subjects, illustrated by the preparations, shall be given every year, by some member of the company.
- “ 3d. That the preparations shall be kept in a state of preservation, and the Collection in as perfect a state as possible, at the expense of the Corporation of Surgeons, subject to the annual inspection and superintendence of the Trustees.
- “ 4th. That there shall be a Board of Trustees, to consist of sixteen members, by virtue of their public offices, and of fourteen others, to be appointed in the first instance by the Lords of the Treasury, and afterwards to be elected, as vacancies may happen, by a majority of the remaining Trustees.
- “ 5th. That the Museum shall always be open for the inspection of all or any of the said Trustees, who are to take care that the Corporation of Surgeons perform their engagements respecting the said Collection. That a day be appointed for the annual inspection of the Museum, by the Trustees acting collectively as a Board; and that they are also to have quarterly meetings, for the transaction of any business relative to the Museum, and for the filling up such vacancies as may happen in the number of the Trustees; and that the Corporation of Surgeons shall engage some person to officiate as Secretary to the Board upon such occasions, and to issue previous notices

to the members, in which he is to state particularly whether any vacancies are to be filled up by new elections."

By a vote of Parliament, 13th June, 1799, the sum of 15,000*l.* was paid for this noble Collection; and grants amounting to 27,500*l.* were subsequently voted for the erection of a building suitable for its reception.

Stupendous as this Collection appears when it is recollected that it was the work of one great mind, yet in the lapse of years it has been found that many chasms were left to be filled up by future labours and researches.

The Museum comprehends systematic series of specimens and preparations illustrative of animal and vegetable structures in healthy and in morbid conditions.

Each series was originally commenced by Mr. Hunter, but many valuable additions have been made subsequently to his decease.

Subjoined is a detail of the present state of the Collection, comprising a summary of the original preparations, and of the additions in the respective departments of the Museum; from which it will be seen with regret how much the want of space precludes a due display of the valuable specimens.

I. *Physiological Series, or Natural Structures from the Animal and Vegetable Kingdoms—IN SPIRIT.*

Hunterian Preparations .	3745
Additional Preparations .	527
	— 4272

The whole of this series is displayed in the gallery of the Museum. It is that which came into the possession of the College in the most complete state, and to which Mr. Hunter appears to have devoted the greatest share of his attention.

The Catalogue of this series, authenticated by the revision of the Founder, consists of quarto fasciculi containing manuscript Prefaces and Introductions explanatory of the several divisions, with general observations on the functions they were designed to illustrate. It comprised descriptions of about a fiftieth part of the series, whereas the portion of the Catalogue now printed contains descriptions of about one-fifth part of the whole.

II. *Natural Structure of Animals and Vegetables, not Osteological—DRY.*

Hunterian .	617
Additional .	128
	— 745

The printed Catalogue of this division

contains both the Hunterian preparations and the additions.

III. *Osteology, Human and Comparative.*

Hunterian .	963
Additional .	973
	— 1936

Of these specimens about a fifth part only is displayed. The Catalogue of this division is printed. In the basement of the Museum are upwards of 400 boxes, containing either the entire skeleton in a separated state, or portions of the skeletons of animals dissected by Mr. Hunter. These, from want of accommodation, have never been displayed or catalogued.

IV. *Natural History—IN SPIRIT.*

Hunterian .	1743
Additional .	355
	— 2098

This series appears to have been designed to convey an idea of the natural affinities of the animal kingdom in an ascending scale. The printed Catalogue includes the *Invertebrata*, named principally according to the nomenclature of Cuvier, but retaining the Hunterian arrangement. This division is regarded as a preliminary to the Physiological series.

V. *Natural History—DRY.*

a. STUFFED ANIMALS.

Hunterian .	87
Additional .	13
	— 100

b. DRIED SPECIMENS OF INSECTS, SHELLS, ZOOPHYTES.

Hunterian and Additional, about 1,000.

No Catalogue of these exists.

VI. *Fossils.*

Hunterian .	1215
Additional .	200
	— 1415

There is a manuscript Catalogue of this series, with an Introduction by Mr. Hunter.

The specimens are chiefly contained in cubes on the floor of the Museum, but the present accommodation does not admit of their proper arrangement and display.

VII. *Pathological Preparations—IN SPIRIT.*

Hunterian .	1084
Additional .	308
	— 1392

The Catalogue of the Hunterian portion is printed, and the Preparations are ar-

ranged on the left side of the floor of the Museum.

VIII. *Pathological Preparations*—Dry.

Hunterian	.	625
Additional	.	95
		— 720

This series had originally the most perfect explanatory documents of any in the Collection, from the pen of Mr. Hunter, who bestowed great pains on its arrangement, preparatory, it has been supposed, to a work on the "Diseases of Bone." There is a printed Catalogue of the Hunterian specimens, which are contained in drawers beneath the north platform.

IX. *Calculi and Concretions.*

Hunterian	.	536
Additional	.	1245
		— 1781

About half of this series is displayed in cases on the floor of the Museum. A manuscript Catalogue of the whole is completed, but the chemical composition of many specimens remains to be ascertained.

X. *Monsters and Malformations.*

Hunterian	.	218
Additional	.	107
		— 325

There is an original Catalogue of this series, containing a classification of monsters by Mr. Hunter; according to which they are now arranged in the printed Catalogue.

In addition to these are about 150 miscellaneous specimens, including casts, surgical instruments, &c. chiefly additions, and a collection of drawings and oil paintings, amounting to about 1000.

Besides the boxes of skeletons before mentioned, the basement contains about 1520 store specimens, chiefly donations.

Of the preparations in spirit, a total of 8087, about three fourths are capable of being arranged and displayed in the present Museum. Of the dry preparations, a total of 7697, not more than one seventh part can be displayed, and even this proportion cannot be usefully arranged; so that little more than one-half of the entire Collection is at present capable of being exhibited to advantage.

Some room may be gained by new arrangements, and also by clearing the Collection of specimens of great bulk and little value; but it is evident that no measure, short of an addition to the actual capacity of the Museum, will be effectual for the purpose of usefully displaying the present Collection, and providing ade-

quately for its increase. This subject has long occupied the deliberations of the Council, and its paramount importance will not fail to ensure their unremitting attention.

In proof of their sense of obligation to the Father of His present Majesty, by whose gracious favour the College was appointed the depository of this great national trust, the Council refer with satisfaction to a liberal expenditure for the due preservation and continual augmentation of the Collection; to its suitable display, so far as the building, erected for this special purpose, permits; to the endowment of Professorships for its elucidation; and to the institution and encouragement of Prize Dissertations, some of which have proved valuable contributions to Surgical literature.

Finally, they refer to the formation and advanced state of the Catalogue—a work of peculiar difficulty, not only on account of the defective state of the manuscript documents authenticated by Mr. Hunter, but from the scantiness of information respecting numerous specimens. Of this important work, now in steady progress towards completion, the following Parts have been printed:—

1. Series of Pathological Preparations, in spirit.
2. Series of Pathological Preparations, in a dry state.
3. Series of Comparative Osteology.
4. Series of Dry Preparations, not Osteological, in Comparative Anatomy.
5. Series of Monstrosities and Malformations.
6. Series of Exterior Natural History, in spirit:—comprising altogether 708 pages in quarto.

A more elaborate Catalogue of the two first subdivisions of the Physiological Series, including the organs of Locomotion and Digestion, accompanied by explanatory notes, and illustrated by engravings, will be published in October next.

The illustration, from time to time, of rare specimens, and of such portions of the several series as are little known, by means of accurate engravings and descriptions, is already commenced in the "Mémorial of the Nautilus Pompilius."

The Museum affords an inexhaustible fund of information to the student of Natural and Medical science, and the Collection, taken as a whole, may be regarded as unequalled. No one who makes himself familiar with its treasures, and is endowed with a philosophical spirit, will quit it without deriving a powerful stimulus to his anatomical studies, and discovering

many interesting paths by which that spirit may be gratified.

It is open to Members, and to Visitors properly introduced, from 10 until 4 o'clock, on Monday, Wednesday, and Friday, in each week; and to scientific foreigners daily. The Conservator attends to supply, as far as possible, the deficiencies of the Catalogue.

LIBRARY.

It has ever been the conviction of the Council, that the splendid Collection of Mr. Hunter was limited in its useful application to Surgery without the addition of a Library, which should be so extensive as to comprehend all the objects for the promotion of which the Collection was formed—the Science as well as the Art of Surgery. It was not, however, until the year 1827 that the Council considered the time to have arrived when they would be justified in devoting a liberal sum to its formation, and an ample annual outlay for its increase. A commencement, indeed, had been previously made; one of the members of the Council, the late Sir Charles Blicke, having bequeathed the sum of 300*l.* in trust for this purpose.

Since the year 1827, the gross sum of 10,172*l.* has been expended in promoting this important object, which the Council believes to have met with general approbation, and to have been found eminently useful as a means of study to the younger, and of reference to the older members of the profession.

The Library comprises a splendid collection of standard and valuable books, as well as of periodical publications in all branches of medical literature, and of the sciences connected therewith. It contains nearly 16,000 volumes, and is continually receiving additions of new publications and of ancient works. It is as accessible

to the Members of the College and to the public as is compatible with due regulations for its security and preservation, with the advantage of a Librarian, who is constantly in attendance, and whose services are rendered more valuable by his intimate acquaintance with general medical literature and with the languages in which most of the interesting works appear.

From the extent and rapid increase of the Library, the want of a sufficient space for its arrangement is as severely felt in this department as in that of the Museum.

The Library is open every day from 10 to 4 o'clock, from the 1st of October to the 1st of April; and from 10 to 5 o'clock during the remaining portion of the year, for all Members of the College and their articulated students; except on Saturdays, when it is shut at 1 o'clock, and except also during the month of August, when it is closed for the purpose of revision. In this and in other points the Regulations of the British Museum have been as nearly as possible followed.

FINANCES.

The receipts of the College are, and ever have been, chiefly derived from the sum paid for the diploma*; and inasmuch as there is no well defined law obliging a student to seek this distinction previously to his commencing practice as a surgeon, the income from this source is uncertain. The expenses of the College and Library, and especially those entailed by the possession of the Hunterian Collection, have been very considerable. It has therefore been a great object with the Council to realize such a permanent income as may be sufficient to meet this unavoidable expenditure, in the event of their usual annual resources being materially diminished.

The average Receipts of the College for the last three years, have	£.	s.	d.
amounted to, per annum	11,116	10	3
The average Annual Expenditure for the same period has been	8,340	18	10

It has been distributed as follows:—

1st. COLLEGE DEPARTMENT†, including Council,

* From the period of incorporation, up to March 1821, a subscription of one pound per annum was paid towards the current expenses of the College by each member resident in and around London, and two pounds by each member of the Council. But as soon as the income and capital justified the remission of these yearly payments, they were discontinued.

† In explanation of this total, it is right to mention, that, upon an average of the last three years, the Court of Examiners met forty-five times in the year, that each meeting occupied at least six hours. Each examiner receives half-a-guinea for every examination for the diploma, and one guinea for his attendance, provided he be present

from the commencement to the termination of the Court; but no fee for the examination of surgeons and assistant-surgeons for the Army, Navy, and East India Company's Service. In addition to the quarterly meetings of the Council, their extraordinary meetings, averaged for the last three years, amounted to twelve in each year, that each meeting occupied from two to three hours, and that each member present during the whole of the proceedings received one guinea for every attendance. The auditors hold four meetings in the year, and each auditor receives one guinea for his attendance. But for the numerous meetings of the several Boards and Committees, occupying much valuable time of the members, no remuneration is received.

Court of Examiners, Auditors, Diplomas, Stamps, Taxes, Salaries and Wages, &c.	£. s. d.	
2d. MUSEUM DEPARTMENT, including the purchase of Specimens, Spirit, Bottles, Catalogues, Printing, Engraving, Stationery, Taxes, Salaries and Wages, &c.	4,750 17 9	
3d. LIBRARY DEPARTMENT, including the purchase and binding of Books, Book-cases, Catalogue, Stationery, Salary, &c.	1,937 10 11	
4th. MISCELLANEOUS EXPENSES, including Repairs, Furniture, Law Expenses, and Incidental Payments, &c.	934 11 0	
5th. EXPENDITURE UNDER DEEDS OF TRUST, including Lectures, Hunterian Oration, and Jacksonian Prize	530 15 0	
	187 1 2	
		8,310 18 10

The present FUNDED PROPERTY of the College is as follows:—

3 per cent. Consols	£ 40,000	
3 per cent. Reduced	23,000	
	63,000 0 0	
The TRUST FUNDS amount to, 3 per cent. Consols	3,307 0 0	
		66,307 0 0

It thus appears that the permanent and certain income of the College does not amount to the sum required to meet the annual expenses of the Museum alone; and as much additional space is required for the proper arrangement and display of the respective contents of the Museum and Library, while other parts of the building

need extensive repairs, a considerable inroad must of necessity be made at a very early period on the capital of the College, reducing still further its permanent income.

(By Order of the Council,)

EDMUND BELFOUR,
Secretary.

LECTURES

ON THE

THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

By DR. ELLIOTSON.

—
DISEASES OF THE URINARY
ORGANS.

—
VARIOUS DIATHESSES.

It appears that there are four elementary kinds of calculi, and four distinct calculous dispositions; to which Dr. Prout gives the name of *diathesis*.

Comparative frequency of various Diatheses.—In the first place, there is the diathesis to form lithic acid and its compounds—lithate of ammonia, a mixture of the two, and soda. Now this is the most common calculus we have: nearly all the calculi taken from children, if they have not been allowed to remain long, consist of lithic acid or its compounds, or a mixture of the two; and in the majority of calculi taken from people, of whatever age, you find that it forms the nucleus within. Then there is a disposition to produce oxalate of lime; and that appears to be a distinct diathesis. Then there is a disposition to form cystic oxide; but this is very rare. Then there is a disposition to form the various phosphates which I have mentioned. This last succeeds to the others: it is usually after the three first diatheses have ceased that the disposition to form the phosphates comes on.

So common is the disposition to produce the lithic acid calculus, that it is said to predominate in rather more than one-

third of all the calculi that are examined, and it is far the most frequent nucleus of all calculi; at least two-thirds originate from it in the first instance. Those which are of a deep fawn colour, well laminated, and have quite a crystalline fracture, are nearly pure lithic acid; in fact, it is red crystallized gravel. If with this diathesis the calculus is of a pale-brown or clay colour, with an earthy fracture, then it is a compound of lithic acid and ammonia; and generally there is a little mixture of the phosphates, and even a little oxalate of lime; and the more there is of the phosphates and the lithate of ammonia, instead of lithic acid, the paler it becomes. The rarest of these calculi is the pure lithate of ammonia. Now the mulberry calculus is found to constitute rather less than one-seventh of all the calculi which are examined, but it is contained in about one-fourth of all the calculi that occur. As to the cystic oxide calculus, so rare is it, that of 274 calculi which were examined only one was found to be of this description; and in three collections out of five none were found. The phosphates constitute about one-fourth of the calculi, and one-half of this one-fourth are the mixed phosphates—that is to say, a mixture of the different phosphates. But this estimate of one-fourth is not very accurate, and for this reason—it has been taken from the external appearance of the calculi; whereas, if these had all been sawn through, it is most likely that within, a number of other ingredients would have appeared. The alternating calculi (those which consist of a layer of different substances—the lithate of ammonia, the oxalate of lime, and the phosphates alternately) form a very large proportion. We sometimes see in these alternating calculi lithic acid and its compounds without, and for a nucleus perhaps a foreign body. We see alternations of lithic acid within, and its compounds, and a mulberry calcu-

lus without: that is very common. We see alternations of lithic acid within, and the phosphates without. We see alternations of the lithic acid calculus within, then the mulberry calculus and the phosphates without. Again, we see alternations of the mulberry calculus within, then the lithic acid and the phosphates without. When, however, these alternating calculi are found, the phosphates exist externally; and therefore it appears that the disposition to form phosphatic calculi does not precede the disposition to form lithic acid calculi, or oxalate of lime. It appears that the disposition to form the phosphates either takes place originally or it follows the disposition to form the oxalate of lime, or lithic acid calculus; but it is not succeeded by any other diathesis. This very interesting and very remarkable fact was noticed by Sir Gilbert Blane, in 1811, in a paper published in the *Transactions of a Society for the Diffusion of Useful Knowledge*. He states that lithic acid is generally the nucleus in calculi, and that the other dispositions are merely the result of irritation. I am not aware that this statement of Sir G. Blane's was attended to for some time, but it has now, by very extensive observations, been proved to be correct. Dr. Prout says that he never met with one patient in whom the phosphatic disposition was decidedly followed by any other: it usually occurs when irritation takes place.

Lithic Acid Diathesis.—Now as to the disposition to form lithic acid, it evidently appears to reside in the kidney; for these calculi are seen in that organ. Indeed, there is no reason whatever for believing that this description of calculus is formed in the bladder: it appears to be truly a renal calculus. If this diathesis be not very intense, you have merely an amorphous sediment, such as we all have at times; and if it be not very abundant, there is no danger. Some people frighten themselves about it; but, unless the quantity be very great, there is no occasion for alarm, especially if the sediment does not appear when the urine is first made. If it be so abundant as to be deposited before the urine cools—if it come from the bladder in the form of powder—then, of course, there may be danger; and if it not only occurs when the urine is first made, and is warm, but takes place constantly, then, I believe, the individual is almost sure at last to have gravel or stone; that is to say, he will pass concretions, or have a concretion so large that it will not pass.

With respect to the lithic acid sediment, there is more danger in proportion as it becomes paler. When it is of a bright red colour, there is not much occasion for

alarm; but when it is white, there is some degree of danger, because it shews a disposition to deposit the phosphates. I do not say that it *always* shews danger, because occasionally when it is white, it is merely lithate of ammonia; and it is white because it is not tinged with the colouring matter in the way I mentioned before. Very frequently, however, the intensity of it arises from the phosphates being deposited; and when that is the case there is considerable danger.

Some people pass not merely a powdery sediment, but a mixture of amorphous and crystallized sediment. Some people will pass even crystals with very little irritation; but if irritation be produced by the sediment, then there is generally a mixture of amorphous and crystallized sediment; and when the irritation is very great, it is generally because a large quantity is passed in both these forms. Under these circumstances there is generally more or less pain in the kidney, and irritation about the neck of the bladder; a frequent desire to make water; the urine is acid and scanty; it has a high specific gravity; and there is more or less feverishness. You will find persons complain of these symptoms from time to time, and then they will discharge a large quantity of red or reddish sediment. The urine is very acid, and you should always test it. This state of things frequently comes on in persons who have a calculus already in the bladder.

But sometimes a calculus is formed and it may remain in the kidney, and give the patient no trouble. A person may have a stone formed in the kidney without being aware of it, and you may be surprised to find it there after death. Sometimes it will only cause an aching pain in the loins, and not shorten life. But occasionally, of course, these calculi produce very great mischief; occasionally, they pass from the kidney, so large as to give great pain. No doubt they continually pass in the form of minute concretions, and the patient is not at all aware of it; and they will lodge in the bladder, and there grow to the size they are found. Sometimes, when they pass through the ureter, they are of such a size as to give great pain on leaving the kidney. From their attempt to leave the kidney, there is pain in the back, attended with vomiting; perhaps you have a great degree of feverishness; perhaps inflammation may be set up, or it may not; and then after a time, perhaps suddenly, all these symptoms cease, and if the stone be very large, then, in a day or two, you have signs of a calculus in the bladder.

The infundibula are sometimes filled with these calculi: you will see them sticking there; and sometimes the kidney will be-

come blocked up with them. The pelvis is sometimes filled with them, the infundibulæ become greatly distended, and sometimes the ureter is blocked up with them, so that the pelvis is distended into a mere bag. It is said that in the College of Surgeons there is a calculus weighing seven ounces and a half, which was taken from a kidney, and which caused no symptoms during life. This is analogous to what I stated with regard to the gall-bladder, where a large number of stones will sometimes exist without being productive of any symptoms. These lithic acid calculi are continually found in the kidney, and they are of all sizes. It is probable that in all instances where they are found in the bladder, they have descended from the kidney.

TREATMENT.

Lithic Acid Diathesis.—Lithic acid calculi, using the term generically, sometimes occur in great numbers; no fewer than 2000 have been voided by one individual in the space of two years, and 120 have been known to come away in three days. It is the calculus which of all others gives the least irritation.

Causes.—Children and dyspeptic individuals are most subject to that state of body in which there is a disposition to form these calculi: the disposition appears to be less between puberty and 40 years of age than before. There is certainly sometimes an hereditary tendency to it; for it occurs in members of the same family, descendants of each other. It is said to have occurred frequently in those who have cutaneous complaints; but cutaneous diseases are so very common, that I do not know whether the number of examples are sufficient to authorize us in supposing that there is any connexion between the two. Something appears to depend upon local situation, for some places are remarkable for the abundance of persons with this sort of calculus, but it is not known in what the peculiarity consists. There is some connexion undoubtedly with a gouty disposition; persons that are disposed to gout frequently become the subjects of this sort of calculus, and this kind of deposition in the urine. Excess in eating or drinking is always mentioned among the causes; and likewise indolence.

Treatment.—As to the treatment of the disposition to form this calculus, and this kind of sediment, it consists in antiphlogistic measures, because this state of body is certainly for the most part inflammatory. An individual so circumstanced should take very little, sometimes, perhaps, no animal food at all. In many cases the latter restriction may be necessary; at any

rate it should be taken in great moderation, and equal moderation is required in eating altogether. In general it is necessary to abstain from wine, spirits, and strong malt liquors, though mild malt liquors may be admissible. It is not merely necessary to abstain from Rhenish and Claret wine, but all strong wines, and every thing that is sour. It is necessary to avoid vinegar, sorrel, oranges, lemons; in short, every thing that is acid. It is likewise necessary that the patient should be moderate in the exercise that he takes, and that he should keep an open state of the bowels.

In regard to medicine, colchicum is found to be beneficial, together with light preparations of mercury—mercury in a moderate quantity, so as not to debilitate the frame, but to keep down as much as possible an inflammatory condition. Neutral salts will be very proper in connexion with colchicum and mercury. Alkalies here are advisable, particularly magnesia, both on account of its being an alkali, and from the tendency it has to open the bowels. A saline draught is an excellent mode of giving an alkali, because although you are giving a neutral salt, yet you are giving a vegetable acid, and that is always decomposed within, so that you have the benefit of the alkali. For this fact we are indebted to Sir Gilbert Blane: he was the first who pointed out the impropriety of giving saline draughts where an alkali was not required, and the advantage attendant upon their exhibition when it was. Dr. Prout, and others who are best able to give an opinion upon it, declare that this is the case, and they frequently give a saline draught for the purpose of administering an alkali. It is judged advisable in these cases to take care that the water which the patient drinks be not hard, does not contain salts or lime, although water for the most part is one of the best beverages which people under these circumstances can take. I stated that neutral salts should be given from time to time;—by neutral salts I mean tartrate of potash and so on.

Patients in this condition sometimes find great relief from the abundant discharge of lithic acid. You will sometimes hear patients say that they have discharged a quantity of powder like fullers' earth. It is certainly true that in this state a vast secretion of lithic acid, or lithate of ammonia, occasionally takes place in the kidney, and then the irritation is altogether relieved. It comes on in fits, just like the gout.

Now some have attempted to bring on a secretion of this earth by artificial means. Some give turpentine and opium

for this purpose, in small doses, and some give onions and leeks steeped in gin, wild carrot, and other herbs, and some give opium itself. Dr. Prout says that he has seen great benefit produced by these substances. I mentioned when speaking of diabetes, that opium has undoubtedly the power of increasing the quantity of lithic acid, and therefore it has been employed where a copious discharge of lithic acid was required all at once—a liberation, if I may so say, of the sediment. But a purgative should be given in conjunction with the opium; because the latter may do harm by confining the bowels—to which they are much disposed—although it may do partial good by exciting a discharge of lithic acid. However, in such a case as this, if the patient be very bad indeed—if he have violent pain in the kidney, great feverishness, pain down the ureter and about the neck of the bladder—you must treat it as nephritis and cystitis, particularly by cupping him on the loins. You will find it serviceable to put him in a hot bath, to purge him well, and give him colchicum, alkalies, and opium.

Oxalate of Lime Diathesis.—In cases where the disposition is to form oxalate of lime and mulberry calculi, the urine is likewise acid; a similar state of the system takes place, and a similar mode of treatment is required.

The mulberry calculus, like the lithic acid, occurs in both sexes, and at all ages up to 50. It is about 50 that it is most frequently seen; but it is, I believe, never formed after 60 years of age.

The lithic acid calculus and its compounds, occur in persons who are very dyspeptic, and who are disposed to be feverish and irritable; but the oxalate of lime and the mulberry calculus is continually produced in persons who have nothing else the matter with them, and when it is produced it may be discharged. The lithic acid calculus and its compounds, I stated, have been formed to the amount of 2000 in one individual—of course, of all sizes; but the oxalate of lime or mulberry calculus seldom occurs more than once in a patient's life, or if it does return—that is to say, if another be produced—it is generally after a very long interval. The urine in this state of things is pretty good, and remarkably clear. The amorphous sediment of the oxalate of lime is a very rare thing indeed, and as to the crystallized sparkling sediment of oxalate of lime, that is still more rare. This description of calculus often acquires an immense size in the bladder, and it does not appear to be produced accidentally. The lithic acid or phosphatic calculus will be produced acci-

dentally, when there is a clot of blood, or a foreign substance has been introduced into the bladder, but this depends upon a peculiar state of the system which is not understood—a peculiar diathesis which appears unconnected with external circumstances. It sometimes follows, and is sometimes succeeded by the deposit of a lithic acid calculus, but nothing is more common than to find it alone. It sometimes happens that oxalic acid ceases to be formed, and lithic acid is produced in abundance, and then the deposition externally is lithate of ammonia instead of oxalate of lime. I have myself known several persons discharge a calculus of this kind. They have been perfectly well, but suddenly have been seized with violent pain in the kidney, which has continued some days, perhaps only some hours, and sometimes only a few minutes; the pain has shot down towards the bladder, and then ceased, and after a few days, in passing their urine, they have been surprised by something making a noise in the *pot de chambre*. Sometimes there has been violent irritation, and all the ordinary symptoms of a stone in the bladder; the stone has escaped, and then they have been perfectly well, and have had no return. I know several persons in whom this happened many years ago, and who ever since have been in perfect health.

Treatment.—The treatment here, as the urine is acid, is exactly the same as for the lithic acid diathesis; that is to say, if there be any inflammatory state of the system, you must suppress it by the ordinary antiphlogistic means. If no inflammatory state can be discovered, still you must put the patient on an antiphlogistic plan. Dr. Prout suggests the propriety of changing the oxalic acid diathesis for that of the lithic acid, by exhibiting muriatic acid. If you give acids, lithic acid is produced, and he says you should endeavour to produce the lithic acid diathesis, which he says may be done by muriatic acid. It is merely a suggestion, and I do not know that it is founded upon practical experience.

Cystic Oxide Diathesis.—As to the cystic oxide diathesis, the calculus itself is very peculiar, and the state of the body in which it is formed is not known. It is generally supposed that it originates in the kidney.

Treatment.—The treatment of the case would depend upon the circumstance of the urine being acid or alkaline. If it be acid, you must treat it in the way I have mentioned; if it be alkaline, then you must treat it as I shall hereafter mention.

Prognosis unfavourable.—Dr. Prout thinks that in this diathesis the prognosis is un-

favourable, for in most instances the kidney has been found diseased, and in others there has been an inveterate hereditary tendency to disease of the urinary organs. It appears to be a very exclusive diathesis, for it is found with no other deposition in the urine; there is no other calculous matter within this as a nucleus, or without it, excepting the phosphates, which are the effect of irritation. The calculus is sometimes encrusted with the phosphates, but that is the result of mere irritation, not of a disposition to disease.

Phosphatic or Earthy Diathesis.—We have now to consider a far worse state of the system—that in which the phosphates are deposited, and which has been called the phosphatic or earthy diathesis.

Now here every thing is the reverse of what I stated to be the case where the tendency is to a lithic acid or oxalate of lime calculus. The urine is not scanty and high coloured, but copious and pale, and often it is greenish. On looking at the urine you may tell what is the state of the parts; you may say that the individual has a phosphatic calculus in the bladder, or is depositing phosphatic sediment. The urine is of lower specific gravity than in the cases I have already considered, and lower than it is naturally. It is in these cases that the urine very soon putrifies; sometimes you cannot keep it a day before it is quite putrid—smelling strongly of ammonia. Frequently at the top of it you have an iridescent and white pellicle, which consists of the phosphates, with, I presume, a little mucus. The sediment may be either pulverulent or amorphous, being a mixture of the phosphate of lime and triple phosphates; or it is crystallized, and then you have the triple phosphates only—white glistening crystals. You know that the two chief calculi found in the bladder are the triple phosphate—the ammoniaco-magnesian phosphate, or that and a mixture of the phosphate of lime, and in that case it is white (not crystallized at all), friable, leaves a white mark on any thing it is rubbed against, and is very fusible.

Now this phosphatic disposition, and these phosphatic concretions, are very rarely original; they generally occur subsequent to the formation of other calculi, and generally subsequent to the lithic acid or oxalate of lime diathesis. The way in which it usually takes place is this: the red sediment becomes of a fainter red, and from the phosphates being more and more formed, it becomes paler and paler till you have a clay colour, and then at last the phosphates only are formed, the lithic acid and lithate of ammonia being no longer deposited. The urine then becomes more abundant, does not shew such strong signs

of acidity, and at last there is no acidity whatever; on the contrary, it is perhaps even alkaliescent, though that is rare when it is first made. Ultimately however, as I have said, it very soon putrifies, and in that case it is very alkaliescent, affecting turmeric paper a short time after it is voided, and depositing spiculae of the triple phosphates.

The two sediments of the phosphates, the sparkling glistening crystals, and that in which there are no glistening crystals, but with which the phosphate of lime is mixed, sometimes alternate. The same individual will for a day, or a week, or perhaps a fortnight, deposit glistening crystals of the triple phosphates, and then at other times those which do not glisten at all, and sometimes the latter alternate with lithic acid; but then the lithic acid is very pale, verging to the phosphates, and sometimes before it gives way to them there is an alternation of the two.

If there be a great deal of crystallized phosphate, then the urine is very alkaliescent; the urea is very copious, and crystals are sometimes formed before the urine is discharged from the bladder. This deposition usually takes place after the urine is made; but in bad cases it will take place before it is voided, and the instant the urine is made they subside to the bottom of the vessel.

In the second phosphatic sediment, that in which there is a mixture of the triple phosphates and the phosphate of lime, though the symptoms are similar, and also the state of the urine, yet they are both far worse than in the first state.

In this condition of the body there is no inflammatory state, there are no marks of inflammation, but a morbid irritability. There is a bad expression of countenance, shewing distress, shewing something wrong in the system. The patient is generally sallow, languid, and experiences pain in the loins. There is generally more or less dyspepsia, and some abdominal derangement. Very frequently there is a want of sexual power and desire; and when a person complains of that, it is always right to examine the urine: in many cases you will find diabetes, in many others you will find an excess of urea, and in others again you will find not only an excess of urea, but a deposition of the triple phosphates.

Of course the urine will vary on different days and at different times on the same day, being at times copious, and at others less so.

Causes.—Many of these cases have arisen from an injury of the loins, and they arise, too, from the depressing passions—from any thing whatever that exhausts the vital powers. In some instances it appears to

have arisen from masturbation, or from excessive venery. Any local irritation will produce it, whether in the bladder or urethra, and therefore this diathesis is rarely found in the kidneys themselves. You will generally find no marks of disease in the kidney, but usually in the bladder. When a lithic acid calculus descends to the bladder it usually produces irritation, and then the phosphates are produced. The bladder is often diseased from various causes, and frequently it is inflamed, so that these calculi appear to be far more frequently formed in the bladder than any where else. They have been formed from an irritation in the urethra reaching to the bladder, but generally it is an irritation of the bladder itself that produces them.

Urine having this deposition has continually been seen after an injury to the spine; and therefore after these injuries, and in disease of the spine independent of mechanical violence, surgeons expect to find such urine, and on examination they generally do. Stricture of the urethra will induce this description of urine; it seems to act, not only by irritating the bladder, but it affects the kidney, causes it to give origin to urine imperfectly acidified. Great irritation, whether it occurs in the bladder or in the urethra, gives a tendency in the kidney to produce urine with a deficiency of acid; and if it be deficient of acid, the phosphates are usually deposited in the way I before mentioned—from the decomposition of the urea and the production of other things.

Treatment.—In this diathesis you must not keep the patient low and bleed him, but on the other hand you must give him meat if he will bear it, and even allow malt liquors. Although perhaps wine in general may be too irritating, yet acescent wines are good; the tendency is to alkalescency, and if they do not disagree with the stomach and intestines they should be taken. Acids themselves are proper, especially citric and muriatic acid. Mercury acts here as a poison. If you give mercury, in nine cases out of ten you will find the urine become more alkalescent, the patient's pulse will become irritable, and all the symptoms about the urinary organs will be aggravated. Opium is required freely, in order to lessen the irritation; the sulphate of quinine, or a decoction of bark, has been exhibited with the greatest advantage, and iron is frequently useful, but occasionally it is too stimulating. These things must be exhibited with regard to individual cases, as well as on general principles. Saline purgatives, of whatever kind, are improper; for as they consist of an alkaline earth and a vegetable acid, and the latter is decomposed in the system, you

are actually giving an alkali, which makes things worse. Saline substances produce great irritation, such as cannot be borne. It is best to give mild aperients, such as *confectio sennæ* and castor oil in moderate doses, so as not to irritate but merely to prevent an accumulation in the intestines. A small quantity of muriatic acid will be found sufficient; 5 drops will produce a specific action on the urine, but 10 or 20 drops may sometimes be required. Opium here is the great remedy, instead of bleeding and mercury. You will find no difficulty in ascertaining whether one particular treatment is proper or not, for the state of the urine will always determine that point. It is always right to employ stained litmus paper, for in proportion as the urine is alkalescent it will restore the original colour, and it constitutes a far more delicate test than turmeric paper.

Necessity of examining the condition of the Urine.—It is the state of the urine which determines all the treatment. Whether there are signs of a calculus in the kidney or not, whether there are signs of a calculus in the bladder or not, whether there are any of the sediments which I have now mentioned or not, whether the person is going to be lithotomized, or has been, the urine should be carefully examined, for you have to treat the case under all these circumstances. Where a calculus has been removed, you still have to remedy the condition of the system which gave rise to it, because that does not cease on the extraction of the stone. You should examine the urine which is made first in the morning, because that is the least liable to be influenced by accidental circumstances, and therefore the most likely to shew the actual state of the system. It should be put away for twenty-four hours, in order that you may make a perfect examination. In many cases you may ascertain the point immediately; but the urine should be allowed to remain and cool, and the sediment, if there be any formed, will then be deposited. This sort of treatment is continually required after lithotomy, or the removal of stones in any other way; and from the want of not making a careful distinction, from the habit of giving alkalies when there is any thing the matter with the urinary organs, infinite mischief is done. It is far better for nothing to be done than to do something wrong; and mistakes, till very lately, were made every day, almost every hour, in the treatment of these cases.

ACCOUNT OF
SOME NEW EXPERIMENTS ON
THE SENSIBILITY OF THE SKIN,

By DR. WEBER, Prof. of Anat. at Leipzig.

By ALLEN THOMSON, M.D.

It is a fact well known to physiologists, that there is a considerable difficulty in pointing out with certainty, when unaided by sight, any spot on the skin that has been touched, and in distinguishing how much of the common feelings of touch is due to the sensibility of the skin, and how much is derived from the muscular sensation produced by the motion of our limbs. It is also well ascertained, that some parts of the skin are better adapted than others, either from their original structure, or in consequence of their being more exercised, to convey to the mind an exact impression of the physical qualities of the bodies with which they are brought in contact. It must be allowed, however, that our knowledge respecting this part of the physiology of the sense of touch is by no means definite.

Professor Weber, of Leipzig, has lately performed a very simple and ingenious set of experiments, which illustrate the subject of the sense of touch, and furnish us with a mode of measuring, with considerable accuracy, the relative acuteness of this sense in different parts of the skin of the same or of different individuals.

These experiments consist in placing the two points of a pair of compasses at different distances from one another, and in various directions, upon different parts of the skin of an individual, who is not permitted to see the bodies touching him*. Professor Weber thus found, that, according to the distance of the two points from one another, we may have the feeling either of one only or of two tangent points, and that the distance at which we become sensible of the double impression is in the inverse proportion to the acuteness of the sense of touch in the skin; or, in other words, that we recognize a double impression made on very sensible parts of the skin, although the points are situated very

near one another, while in those parts of the skin in which the sense of touch is obtuse, the points may be removed to a considerable distance from one another, and yet convey to us the feeling of only one impression.

In August 1831, Professor Weber was so kind as to shew me some of the more striking of his experiments, and at the same time presented me with an account of them, originally published in detached parts as "Annotations" to some of the inaugural dissertations of the Leipzig University. He had also printed these annotations in a separate form, but I am not aware whether they have ever been published. To the best of my knowledge no notice of these experiments has as yet appeared in this country, which induces me to believe that a short account of them will be acceptable.

Professor Weber has embodied the principal results of his experiments on the varieties in the acuteness of the sense of touch of different parts of the skin, in eight propositions, of which the following is an abstract.

PROP. 1. The different parts of the skin, or organ of touch, do not possess an equal power of distinguishing two bodies by which they are touched at the same time. The distance of the two touching bodies being known, the degree of this power may be measured; for it is ascertained that if the organ of touch does not perceive the contact of two bodies when they are near one another, it becomes sensible to the impressions of both when the distance between them is increased.

If the touching points are sufficiently distant, we not only distinguish the impressions of both, but also the direction, longitudinal or transverse in relation to the body, in which they are applied to the skin. When they are brought nearer to one another, they first give the sensation of the contact of a long body; but when brought still closer together, they appear as a single point upon the skin.

The ends of the fingers, and the tip of the tongue, have the power of distinguishing the distance of two points nearly equal, and in a much greater degree than any other part of the body. At two-fifths of a Paris line we are capable of distinguishing the longitudinal from the transverse position of the points on the tip of the tongue. At half a line two impressions are felt, more especially

* The sharp points of the common compasses may be blunted with a little sealing-wax, which will have the effect also of taking away the cold feeling of the metal.

when the points are made to touch at the same time the upper and lower margins of the tongue, or the dorsal and palmar sides of the fingers; but in most other parts of the body this is different; for

PROP. 2. In many parts of our bodies we perceive the distance and situation of two points touching us at the same time, more distinctly when they are placed parallel to the transverse than to the longitudinal direction of the body.

This may easily be tried in the middle of the arm or fore-arm; here the two points may be distinguished at a distance of two inches when placed in a direction across the arm; but they appear as one at this distance, or even (in some persons) at three inches, when placed longitudinally.

Under this proposition Professor Weber has placed a very long table, which may be considered as a detailed register of his experiments, and in which are exhibited the distances at which he was sensible of a single or double impression from the contact of the two points with different parts of his skin. It is difficult on a cursory view of that table to follow the general results, and on this account I have preferred giving only a shorter and more illustrative one which follows it, in which the parts of the skin are arranged according to the acuteness of their sense of touch, as measured by the smallest distance at which the horizontal or transverse position of the two points and a space between them could be distinguished.

PROP. 3. In those parts of our body in which the impressions of both points are clearly distinguished although not distant, the space between these points appears to be greater than in other parts possessing a less sensible touch.

The experiments illustrative of this are very striking. They may be best performed by drawing both the points of the compasses gently along the skin, from a sensible to a less sensible part, or *vice versa*; as from the hand along the fingers; from the cheeks or ear across the lips, and towards the nose; from the jaw to the chin; from the occiput to the sacrum, with a point on each side of the median line; and from the chin to the pubis, in the same manner. In passing over the more acutely sensible parts, the points of the compasses seem to open or to recede from one another; and the reverse takes place in those regions in which the sensibility is obtuse.

PROP. 4. If the points are placed on two contiguous parts, which may be moved voluntarily and independently of one another, the double impression is much more clearly perceived, and the points appear more remote from one another, than if, at the same distance, they were brought in contact with one entire part. This is easily shewn on the lips, fingers, and eye-lids.

PROP. 5. We distinguish the two points more clearly, if they are brought into contact with two surfaces having a different structure and use, than when they are applied to one and the same surface.

This rule also holds in respect to surfaces possessing different degrees of sensibility; for in this case also, the points are more clearly distinguished when they touch two contiguous surfaces of different powers, than when they are both placed on the most sensible of them. This may be seen on the lips, by placing one point on the internal, and another on the external surface, in which position the points are distinguished at a smaller distance than in any other, although the surface of the lips directed towards the gums has a much less acute sense of touch than the red part. The same is the case with the white and red external surface of the lips.

To the same general rule may be referred another fact, viz. that a smaller distance of the points is perceptible when they touch at once the palmar and the dorsal surfaces of the fingers, than when they are both applied to one of these surfaces; and it may also be stated, under this head, that this power of distinguishing the points is generally greater when they are applied at equal distances on each side of a median line of the body.

PROP. 6. If we examine attentively the degree of acuteness of the touch in each part of the body, we shall find that this varies not only in the larger parts, but that there are also small spaces, in some of which the sense is more acute, in others in the immediate neighbourhood more obtuse. These points, however, do not vary to a great extent in the degree of their acuteness, nor has Professor Weber discovered any fixed order according to which they are disposed.

This observation would seem to shew

that the nervous fibriles are not quite equally distributed throughout the skin*.

PROP. 7. If we are touched with greater force by one of the points than by the other, the impressions of both are distinguished less easily; for the stronger obscures the weaker.

PROP. 8. We distinguish two separate impressions more easily when they are not made exactly at the same time; and on this account, in performing all the experiments previously referred to, it is necessary to pay great attention, in order to make the contact of both points synchronous.

After announcing these general propositions, Professor Weber proceeds to describe some varieties in the sensations communicated by the contact of the two points in particular regions of the body.

Touch in the Extremities.—The middle of the arm, thigh, fore-arm, and leg, or a place near it, at which the greatest quantity of muscles is collected, has the bluntest sense of touch; the fore-arm is a little more sensible than the arm, the leg than the thigh, and the fore-arm is on the whole more sensible than the leg. The convex part of the joints, as the skin over the patella, olecranon, and acromion, are more sensible than that in the popliteal space, the bend of the arm, and the axilla. The internal surface of the arm, and the posterior surface of the leg, do not differ much respectively from the external nor anterior. The arm and leg are far excelled by the hand and foot, and the hand is greatly superior to the foot. In the hand, touch is much more acute on the palmar than on the dorsal surface. The skin over the heads of the metacarpal bones is more sensible than that in the middle of the palm; and the sensibility gradually increases from thence towards the points of the fingers. The heel is more sensible than the middle of the sole of the foot. The dorsum of the hand and foot are surpassed by the lower ends of the forearm and leg. In general, the distal end of the arm and leg is more sensible than that towards the trunk, yet the skin over the deltoid muscle surpasses that towards the elbow.

In the extremities, the transverse is

* The presence of these slight variations appears to be indicated remarkably in some parts of my skin, by a very curious feeling of irregularity, which occurs when one or two points are drawn along these parts.

always much more easily perceived than the longitudinal position of the touching points.

On the Head.—The hairy scalp is the least sensible part of the skin of the head; it is more sensible, however, than that of the neck. The skin near the forehead and temples is more sensible than that on the vertex. The sides of the jaws come next, and the parts of the face are more and more sensible as they are nearer the median line, the point of the nose and the red part of the lips. The inner sides of the lips are less sensible the further they are from the margins. The gums are susceptible of considerable pain, but possess very little power of distinguishing the distance of the two points. It would appear that we can sometimes ascertain the distance and direction of the points by means of the teeth or their pulps. The most sensible part of the point of the tongue occupies only a small space—four or six square lines. The touch of the tongue becomes less acute on all sides as we recede from this. The soft palate has a more acute sense of touch than the hard palate.

On the Trunk of the Body.—The sense of touch on the surface of the trunk of the body is less acute than that of the head and extremities; and there is no part of the trunk possessed of the same acuteness as the tongue, lips, fingers, nose, or hand. The mammae even have not an acute sense of touch. From this, as well as several other observations, the important deduction may be made, that the acuteness of the sense of touch is very little connected with or in proportion to the susceptibility of the skin to be affected with pain or titillation, and tenderness of the skin by no means indicates acute sensibility, or acuteness of the sense of touch.

One of the most important differences between the sense of touch in the trunk and that in the extremities consists in this—that on many parts of the trunk the horizontal or transverse position of the points is not more easily recognized than the perpendicular or longitudinal.

In a considerable series of experiments which Professor Weber made in illustration of the relative acuteness of the sense of touch in different parts of the trunk, he chose three horizontal lines encircling the body in the regions of the neck, thorax, and abdomen, and four vertical lines, passing from the head

downwards to the inferior extremities, and measured the power of touch as before, by placing the two points at different distances and in various directions on these lines.

In placing the two points at a distance of about two inches, in a horizontal position, on the line surrounding the thorax, from the ensiform cartilage, a little below each mamma, he found that there are four places at which the distance of the two points is most obvious. These places are in the middle, before and behind, and on the two sides. We perceive the two points most distinctly when they are placed equidistant on each side of the median line; the clearness of the double impression diminishes as soon as they are moved to one or other side. Nearly the same, though with less distinctness, is the case in the middle of the two sides.

On applying the two points in a vertical direction across the horizontal line surrounding the thorax, there are four places in which the double impression is less clearly perceived than in others; or the sensibility appears most obtuse in the same region in which the horizontal application of the points is most clearly perceived; and *vice versâ*. This inverse ratio does not, however, hold in all the intermediate regions*.

In the second horizontal line surrounding the abdomen about an inch above the umbilicus, the longitudinal and transverse application of the two points give nearly the same results as in the thorax. But in the third line surrounding the neck, Professor Weber states that the results were so inconstant as to render an account of them unnecessary.

In the anterior median line, extending from the chin to the symphysis pubis, the transverse position of the points gives the clearest impression on the chin, and next on the upper part of the neck. The points seem to approach one another as they are brought to the bottom of the neck and top of the sternum; the sensibility is increased on

* It must be remarked, that, in Professor Weber's account of his experiments, there is an apparent contradiction in respect to this; for at one place he says there are four places in which the vertical position is least clear,—two behind and before, and two on the side; and at another he says that it is clearest of all on the sides. I have found the vertical position of the points more clearly distinguishable on the line passing from the axilla to the ileum, than either before or behind it.

the sternum, and again diminished at the lower part of the thorax and upper part of the abdomen; a little above the umbilicus it increases again rapidly towards this part; below it, the points appear again to approach one another, and coalesce into one on the symphysis of the pubis.

The application of the two points in a vertical or longitudinal direction on the anterior median line, showed nearly the same alternate increase and decrease of the power of touch.

On the posterior median line, extending from the occiput to the coccyx, the transverse and longitudinal position of the points is most easily recognized near the occiput and between the glutæi muscles. The sense of touch increases to a considerable degree from the sacrum towards the anus; and there is also a place between the scapulæ, on which it is considerably greater than above or below.

In the median lines, therefore, it appears that nearly the same varieties of the sense of touch are perceived by the longitudinal and transverse application of the points; which would seem to show, that in these lines of the body the varieties in the sense of touch ought to be attributed not merely to the difference of direction of the course of the nerves, but also to their existing in greater or less quantity, and their being endowed with a more or less acute sensibility.

On the lateral longitudinal lines, extending from the axilla to the crest of the ileum, the sense of touch seems to be greatest towards the axilla, and towards the crest of the ileum.

The causes of this diversity in the sense of touch in different parts of the body, seem on the whole not to be well ascertained. It is sufficiently obvious that the greater sensibility of some parts of the body does not depend on their being more frequently seen than others, as some have supposed to be the case; the middle of the back of the hand, constantly exposed to view, is surpassed by the fingers and palm, and even by the lower end of the forearm; the same is the case with the dorsum of the foot. The skin over the os sacrum and coccyx, though beyond the range of vision, is comparatively very sensible. The sensibility of the sub-mental surpasses that of the sternal and abdominal regions; and though the anterior is generally

more sensible than the posterior surface of the body, this would appear to be connected with the structure of the skin rather than with the sight, for the sacrum and coccyx are more sensible than the pubis. Examples of blind persons also, and the great improvement their organs of touch are susceptible of from exercise, sufficiently show that sight has very little to do with our power of distinguishing by touch different regions of the skin. Nor does this power appear to depend chiefly on any mechanical advantage of one part over another—as, for example, that some parts are fixed on bones, and others are very moveable. The tip of the tongue and free part of the lips which are loose, and the points of the fingers which are fixed, are possessed of nearly equally acute powers of touch.

The cause of these variations is probably to be sought for in the structure of the skin, with which subject we are as yet, as regards the distribution of the nerves at least, very imperfectly acquainted. It seems to be obvious, however, that the great power of touch does not depend on the presence of papillæ, for the mammæ, and some other parts with numerous papillæ, have yet a very blunt sense of touch. The tongue has papillæ over its whole upper surface; but it is only at the tip that the sense of touch is very acute.

Many experiments seem to show that the direction of the course of the larger and smaller nervous twigs has some influence over the power of the skin, by which we distinguish the separate impressions of the points. The greater power which we have of distinguishing the points in a transverse than in a longitudinal position on the arms and legs, while on the face and some parts of the trunk of the body a position of the points parallel to the longitudinal direction of the body gives the clearest double impression, would seem to show that in general the feeling of the distance of the points is most acute, when they are applied across the direction of the nerves in their course. There are, however, other varieties which cannot be so easily explained in this manner, and it becomes necessary to have recourse to the supposition, that the quantity of nervous matter, as well as the mode of its distribution in the skin, may influence to a considerable extent the acuteness of the

sense of touch. Sufficient attention has not as yet been given to this part of the subject.

The effect of motion of our organs, and of the bodies touching them, in augmenting the acuteness of the sensation, is very remarkable. When two points, for example, placed upon the skin appear as one, we can often recognize their double impression by moving the skin. It is thus that by moving the fingers we discover the asperities on surfaces which could not be felt, were the finger held at rest over them. We also acquire a more accurate knowledge of the nature of an impression, by having it made on different parts of the skin in succession. By a peculiar internal feeling, called the muscular sensation, informing us of the extent of muscular contraction, we come to know the direction and space in which our limbs are moved; and every one knows that this feeling is of very considerable importance in aiding the sense of touch, and in improving that kind of touch frequently distinguished in this country by the term *tact*. It has already been remarked, that it is not unfrequently difficult to discriminate whether we judge of the qualities of a surface by the sensibility of the skin, or by the muscular sensation. We can in general tell immediately the direction in which any one pulls the hair of our head; but the knowledge of this direction is not derived, as might be supposed, from the sense of touch, but depends on an exertion of the muscles of the head, which is immediately and insensibly made with the view of resisting the motion of the head, which without it would occur. On fixing the whole head, it will be found that the power of distinguishing the direction still remains, though in a less degree. This seems to depend on the position of the skin in the neighbourhood being altered by traction; for when we fix the skin, the power of distinguishing the direction in which the hair is pulled, entirely disappears.

Another illustration of this is obtained from the following experiment:—Shut the eyes, hold the hand steady, and let some one touch your fingers with and carry along their points various substances, as paper, glass, metal, wood, quill, leather, linen, silk, or velvet; you will be surprised how often you mistake the one for the other, according as they are more or less lightly pressed against

the fingers. Metals, when of the same temperature as the hand, can scarcely be distinguished from glass and other substances with a smooth surface. When the finger of one person is conducted by another into a fluid, the slight pressure over a considerable surface informs him of its presence. If a person draws a plane surface along the finger of another, pressing at first gently, then gradually more strongly, and again gently, the feeling of a convex surface will be communicated to the finger, and that of a concave surface may be given by the greatest pressure being made at each end.

Professor Weber next relates some experiments which he performed with the view of ascertaining how far we are capable of judging of the weight of bodies by the sense of touch in the skin, and how far it is necessary that we should be assisted also by the muscular sensation; for it is obvious that in general we make use of both these means to obtain a correct estimate of weight.

He found that when two equal weights* are placed on corresponding parts of the skin, he might add to or subtract from one of them a certain quantity without the person on whose skin they were laid being sensible of any change or inequality in them. He ascertained that when the hand or any other moveable part of the body is laid quite inactive on a table, a much greater change can be made in the relative weight of the two bodies, without its being perceived, than when the limbs are free and capable of muscular exertion: that 32 ounces or drachms, for example, may be altered by from 8 to 12, when the hand is motionless and supported, but only by from one and a half to four when the muscles are in action; and hence Professor Weber infers, that the measure of weight by the touch of the skin alone is more than doubled by the assistance of the muscular sensation.

By these experiments it was found that the lips estimate weight more correctly than any other part of the body: the fingers and toes may be reckoned next, the second phalanx being inferior

* The weights employed ought to be made of the same material, and must present the same size and form of surface to the skin. In order to insure this, and to correct the difference of temperature, it is well to interpose similarly shaped pieces of pasteboard between the weights and the skin.

to the third, and the first to the second: the palm of the hand and sole of the foot, especially the parts covering the ends of the metacarpal and metatarsal bones, possess also a considerable power, while the back, thorax, abdomen, scapulæ, arms, legs, and occiput, have very little power of estimating weight; which observations obviously show a considerable correspondence between those parts of the skin possessing the most acute sense of touch, and those estimating weights most correctly.

Professor Weber attributes to a more acute sense of touch in the left arm the circumstance, that to most persons weights appear heavier to the left than to the right arm. This is no doubt to a certain extent caused by the common preponderance of the muscles of the right arm over those of the left; but Professor Weber states that he has also proved that in a large proportion of the individuals on whom he has experimented, the sensibility of the skin on the left arm is greater than that on the right, and he has found, that though the hand is not assisted in any degree by the muscular action or sensation, as when it is steadily supported, weights still appear heavier to the left than to the right arm. Of fourteen individuals of different classes of society, eleven found the weights heaviest in the left hand, two heaviest in the right, and in one there was no difference between the right and left. He also ascertained that this acuteness of touch in recognizing weight resides not only in the left hand, but also in the left foot and scapula.

In concluding this account of Professor Weber's researches, which I regret I have been obliged to shorten too much, I may state that I have repeated a considerable number of the experiments on the comparative sensibility of different parts of the skin, on my own person, as well as on other individuals, and have obtained very nearly the same results. The acuteness of the sense of touch over the whole skin seems to me to vary more or less in different individuals; but I have not observed any striking deviations from the results recorded in Professor Weber's papers, in respect to the relative acuteness of this sense in the different regions of the body*.

EXPERIMENTS ON THE CONSISTENCE OF COAGULATED BLOOD.

To the Editor of the Medical Gazette.

SIR,

If you think the experiments, of which I now send you an account, are deserving of the attention of the profession, I shall be much obliged to you to spare them a corner in your excellent periodical.—I am, sir,

Your obedient servant,

HENRY JOHNSON, M.D.

Shrewsbury, August 27, 1833.

In order to make some experiments on the consistence of blood in different diseases, I contrived the instrument of which I here give an accurate description and figure.

It consists of a small round cone of ivory, A, into the base of which, at *a*, is screwed a cylindrical stem, B, turned very smooth, and made of ebony. The stem B is surmounted by a circular flat piece, C, which screws on the extremity of B, and may be removed at pleasure. The whole instrument is $4\frac{1}{2}$ inches in length. The length of the ivory cone, A, is $1\frac{1}{8}$ inch; at its broadest part its diameter is three-eighths of an inch, and from this it gradually tapers to a sharp point at *b*. Lastly, it has a scale of degrees engraved upon it, each of which is nearly equal to $1\frac{1}{10}$ of an inch, there being $17\frac{1}{2}$ on the whole scale. The stem B, with the disk C, is just three inches long; the diameter of the former nearly $\frac{2}{5}$. Weight of the whole, 71 grains.

The mode of using this instrument, and the principle on which it acts, are obvious. It is to be held loosely in the fingers like a pen, or by means of a piece of card perforated to admit the

* From Edinb. Med. and Surg. Journ. for July.

stem and allow of its easy motion. In either of these ways the point of the cone is to be brought down gradually, and in a perpendicular position, upon the blood to be tried. The weight of the instrument of course forces the conical part into the blood to a greater or less depth, according to its consistence; and the depth to which it sinks, as ascertained by the graduated scale, affords a pretty accurate measure of the consistence or cohesive power of the coagulated blood.

I shall now, as briefly as possible, relate some experiments performed with this instrument, which I shall in future designate as the hæmometer*.

Eight ounces of blood were taken from a person not very robust, but in good health. In two hours it had become perfectly coagulated, and had separated much serum. The hæmometer applied to the coagulum indicated ten degrees. At the end of four hours, more serum having separated, it indicated only 9 degrees; in seven hours, still 9 degrees; in ten hours, $9\frac{1}{2}$ degrees. Twenty-three hours after the commencement of the experiment, it was again at 9 degrees.

Having stated the foregoing experiment at full length, I shall give the results of the others in the following table:—

No.	Name of Subject.	Disorder.	How long drawn.	Degrees indicated.	Remarks.
1	A. B.	Rheumat. acute	24 hours	0	{ Coagulum contracted, dense buffy coat.
2	C. D.	Rheumatism	20	$\frac{3}{4}$	Thick buffy coat.
3	C. B.	{ Hæmop. & slight } { pneumonia. }	1	1	{ Coagulum contracted, covered with buffy coat.
4	M. O.	Contused side.	3	1	{ Buffed and cupped, a plethoric young woman.
5	J. J.	Hepatitis, acute.	3	1	Much buffed, serum green.
6	E. E.	Unknown.	23	1	Much buffed.
7	E. F.	Pleurisy.	$5\frac{1}{2}$	$1\frac{1}{2}$	{ Coagulum contracted; much buffed.
8	E. M.	Angina pect.	$2\frac{1}{2}$	2	Considerably buffed.
9	W. H.	Hæmoptysis.	3	2	Not at all buffed.
10	G. H.	{ Cough and pain } { of side. }	5	2	Buffed in patches.
11	J. J.	Rheumatism, acute	18	3	Not buffed.
12	J. J.	Ditto.	$1\frac{1}{2}$	$3\frac{1}{2}$	Same blood as No. 11.
13	G. H.	{ Cough and pain } { of side. }	2	$3\frac{1}{2}$	Buffed in places: see No. 10.
14	W. J.	Rheumatism slight.	$3\frac{1}{2}$	5	Not buffed.
15	E. E.	{ Headache and } { pain of side. }	$16\frac{1}{2}$	$5\frac{1}{2}$	Coagulum contracted; no buff
16	E. G.	Rheumatism.	20	6	Not buffed.
17	W. R.	Congestio cerebri.	5	6	Almost no appearance of size.
18	J. J.	Cough and palpit.	$2\frac{1}{2}$	7	No buffy coat.
19	J. D.	{ Ulcerated leg, } { and pain inside. }	1	7	{ Perfectly coagulated; no buffy coat.
20	C. D.	Slight concussion.	3	8	Not buffed; serum separated.
21	H. T.	None.	4	9	Serum separated; no buff.

I have arranged these experiments according to the indications furnished by the hæmometer, not according to the order in which they were performed.

In conducting these experiments, it has always struck me that there was generally a connexion between the state of the system and the greater or less

consistence of the blood. I mean, that a high degree of consistence of the clot shews an inflammatory or sthenic tendency; a lower degree indicates a more moderate state of excitement, whilst a state of debility, or asthenia, is attended with a weaker cohesive power. Let the reader, for example, compare Nos. 1, 2, 3, 4, 5, 7, &c. with the slighter affections (14, 15, 18, 19, 20), and with

* From *αἷμα* and *μετρεω*.

No. 21, in which the blood was taken from a healthy person. The above experiments shew a difference in the consistence of the blood much greater than I had even suspected. The healthy standard is probably about 9 degrees. In acute rheumatism, and other inflammatory diseases, its consistence is so great as to be indicated by 1 deg. of the hæmometer. On the other hand, in some cases*, not set down in the table, I have seen the blood so dissolved and void of cohesion as to allow the instrument to sink to the bottom of the vessel, as in a thick liquid.

The presence of the buffy coat makes the hæmometer sink to a very little depth, and thus marks a high degree of cohesive power; but it is remarkable that in No. 9 the instrument shews a very great consistence where there is no visible buffy coat.

I am fully aware that the opinion here offered, as to a difference of consistence of the blood under different states of the system, is neither novel nor original. I have sometimes seen the talented professors of clinical medicine at Edinburgh†, employ the finger to ascertain this point. I think, however, that it may be satisfactory to have more direct experiments on this subject.

In conclusion, I would venture to suggest that an instrument such as I have described may be employed in ascertaining the condition of the system whilst labouring under disease, and in certain obscure cases may assist in determining the propriety of venesection, or other depletory measures. Such a test, it is evident, possesses many advantages over the appearance or non-appearance of the buffy coat.

Another use which may be made of this instrument, is to ascertain with accuracy the degree of induration or softening of the brain in post-mortem examinations; an application of which I must defer the consideration to a future opportunity.

I hope that these experiments will lead others to turn their attention to this subject; that they will try the utility of the hæmometer, as a means of affording practical indications in the diagnosis or treatment of disease; and that they will communicate their observations, whether they be for or against the views here entertained.

* One of these was a case of fever.

† This was about 1828 or 1829.

TRAUMATIC TETANUS SUCCESS- FULLY TREATED WITH CAR- BONATE OF IRON.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of transmitting to you the particulars of a case of traumatic tetanus successfully treated with the carbonate of iron. Should you think it of sufficient importance to insert in the Medical Gazette, it is at your service.—I am, sir,

Your obedient servant,

E. F. DEHANE, M.R.C.S.

Wolverhampton, Aug. 1833.

Robert Ireland, a stout healthy countryman, ætat. 43, living with Thomas S. Hellier, Esq. of the Woodhouse, in this neighbourhood, in the capacity of waggoner, whilst driving home a load of manure early on the morning of the 25th May last, was riding on the shafts of the waggon, and being somewhat intoxicated, fell off: the wheels passing over his left leg, caused a fracture of the tibia and fibula a little above the ankle-joint: the great toe of the right foot was much lacerated and the bones comminuted: the wheel having also passed over it, a small portion of the crusta of the left ilium was broken off, and the integuments covering it torn and bruised. The patient having been conveyed home, a distance of about three miles, was immediately placed in bed, and the fractured bones of the leg reduced, and a poultice applied to the toe: an anodyne was administered, followed by aperients. There is considerable suppuration from the toe, and he appears to be going on favourably.

June 4th.—He now complains of a slight stiffness of the jaw, which seems to be gradually increasing, but is unattended with pain: the wound of the toe looks well, and granulations are appearing in the midst of a very copious discharge of pus: the pulse is 70, and natural; bowels regular, tongue slightly furred. Ordered as follows:

R Decoct. Cinchon. lb. ss.; Tinct. Opii, gtt. 100; Pulv. Cinchonæ, Ammoniac Carbon. a. ʒij. M. cap. unciam unam 2dis vel 3tiis horis.

The neck to be rubbed with an anodyne embrocation, and some ale allowed.
8th.—The jaw is now nearly closed,

and the muscles quite rigid, and he complains of severe pain at the back of the neck, extending to about the middle of the dorsal spine: the pulse is about 85: he has continued the bark mixture with opium, with the addition of half a drachm of the powdered bark to each dose.

The case now having assumed a very serious appearance, and the tetanic symptoms evidently increasing, it was determined, in consultation with Dr. Dehane, to adopt the plan which had been found successful in two cases by Dr. Elliotson, viz. by the exhibition of the carbonate of iron, twelve ounces of which were given in the course of the day.

9th.—The abdominal muscles have become rigid and affected with violent paroxysms of spasmodic pains, as are also those of the neck and jaw, which remain immoveable. The head is drawn backwards, and he grasps the bedstead with his hands thrown behind him: his sufferings are indeed very great, and his shrieks may be heard at a considerable distance: his pulse is 100, but the state of the tongue cannot be ascertained, from the rigid closure of the jaws: ℞. j. ferri carbonatis is directed to be taken during the day in beef-tea and treacle, and the parts affected to be frequently rubbed with tincture opii; his bowels to be regulated by castor oil. The granulations in the wound are still rising, and the discharge of pus copious.

10th.—The patient has been more tranquil in the night, and the pains arising from the spasms and tension are much mitigated: pulse has fallen to 70, and his bowels are open; but the rigidity of the muscles remains.

Ordered—Ferri. Carbon. ℞ij. quotidie.

11th.—Has had a bad night, in consequence of the return of pain in the back, but he is this morning better: the rigidity continues in the muscles of the neck, jaw, and abdomen; bowels have been acted on by castor-oil, a considerable quantity of a lumpy, ferruginous-looking substance, having been discharged.

Contin. Ferri Carbonatis, ℞. j. quotidie (ad libitum.)

12th.—This night has been indifferent, from the spasmodic pains in the abdominal muscles; there is, however, a slight relaxation of the jaw, and a cessation of

pain in the cervical muscles; bowels confined.

℞ Infusi Sennæ, ℥vj.; Mag. Sulph. ℥j.; Træ. Sennæ, ℥ij.; Pulv. Jalap. ℥ss.
M. capiat cochlearia duo ampla 2dâ quâque horâ, donec subducatur alvus.
Rep. Ferri Carbon. ut antea.

13th.—Has passed a good night, and is much better, the spasmodic pains having ceased; the abdominal muscles, however, are as hard as a board; the bowels have been well opened, and he has continued the iron, but in diminished quantity; pulse 65; appetite good, though only liquids can be taken.

15th.—He yesterday of his own accord discontinued the carbonate of iron, and has had a return of spasms, both in the neck and abdominal muscles, attended with most excruciating pains; pulse 90, and his bowels open. Directed the iron to be immediately resumed, to the extent of ℞. j. per diem.

16th.—Has passed a tolerable night, and there is a considerable mitigation of the pains, but the rigidity of the muscles still is present, it being barely possible to insert the point of the little finger between the edges of the incisor teeth.

Contin. Ferri Carbon. et Mist. Aper.

17th.—Has had a very good night; the pains have entirely left him; his pulse is 80; and he has passed a large quantity of indurated feces, similar to the before described; and there is a perceptible relaxation of the jaws.

July 7th.—Since the date of last report, there has appeared to be a general, but gradual amendment, though with occasional returns of the spasmodic pains, and the rigidity of the abdominal muscles continued for more than a week subsequently, as well as those of the neck; the muscular tension has now, however, so much relaxed that he can rotate the head with facility, and has regained the partial use of the jaw, so as to be enabled to masticate his food. The wound of the toe has thrown out luxuriant granulations, which have required to be kept down by the application of caustic, and is now beginning to cicatrize. The fractured leg is doing well, union having taken place. He has continued the use of the carbonate of iron, but in smaller quantities, about ℥ij. per diem, with the occasional use of an opiate draught and castor-oil, as before; and

he has been allowed some wine, in addition to the ale before mentioned.

21st.—The tetanic symptoms have disappeared for a considerable time, and he is enabled to walk about, the fracture being firmly united, and the wound of the toe completely cicatrized, several splinters of the bones having come away from it at the different dressings.

HYDROCYANIC ACID.

To the Editor of the Medical Gazette.

SIR,

THE Medical Gazette of the 10th of August last contains a communication from Mr. Laming, in which he proposes a formula for the preparation of medicinal prussic acid: "a plan," he says, "which, for its simplicity and perfection, is probably destined to supersede the five very uncertain methods now in use." The process is that of decomposing cyanuret of potassium by tartaric acid. Now if Mr. Laming, or your readers, will refer to the Glasgow Medical Journal, No. 14, or to the Philosophical Magazine for August 1831, they will find that this very method has been already adopted and described by Mr. Clark, of Glasgow.

Mr. Laming observes, that "there has been an impediment in the adoption of such a formula, in the delicacy of the cyanuret of potassium; no plan heretofore having been discovered for its formation in a state of purity." The word *delicacy* I presume to be a misprint for *imperfection*; but the allegation, even thus amended, is totally groundless. Mr. Laming, without giving the details of his analysis, states that he found the composition of cyanuret of potassium to be, cyanogen 3.25 + potassium 5 = 8.25; a result which agrees most precisely with that previously given by Dr. Thomson (Chemistry of Inorganic Bodies, vol. ii. p. 868). It is, however, rather difficult to imagine how Dr. Thomson could have arrived at this conclusion, unless he had procured the salt in a state of purity.

Indeed, from the statement of Mr. Clark, in the paper alluded to, from that of Dr. Thomson (Chemistry, vol. ii. p. 867), and of Berzelius (Traité de Chimie, tom. iii. p. 383), it is evidently

easy to obtain pure cyanuret of potassium by heating the ferrocyanuret, treating the residue with water, and evaporating the solution, or crystallizing the salt. Mr. Laming concludes with mentioning that his method of procuring pure cyanuret of potassium has been communicated by him to the gentlemen engaged in preparing the new Pharmacopœia; and with them, he says, it "must rest for the present." From the want, however, of originality in Mr. Laming's formula for preparing prussic acid, and in his analysis of cyanuret of potassium, I confess that I am not very sanguine as to finding any improvement in his process for procuring this salt, when the depositaries of the secret may think proper to reveal it.

I am, sir,

Your obedient servant,

RICHARD PHILLIPS.

UNCERTAINTY IN THE DURATION OF LABOUR.

To the Editor of the Medical Gazette.

SIR,

EVERY accoucheur's experience must furnish him with instances confirmatory of the propriety of taking great care in delivering an opinion as to the time a labour is likely to terminate. Carelessness as to this point may destroy the confidence of the patient, prolong her sufferings, or place her in jeopardy; and very needlessly cause delay and anxiety to the attendant. The data for forming such opinion are often exceedingly uncertain: thus a case, on the one hand, proceeding apparently rapidly to its termination, may be interrupted by many occurrences (often of a very trivial nature) for several hours; so also, on the other hand, it may be brought to a close with far greater rapidity than the time and uterine action expended would lead us to expect. Several cases have lately occurred to me, impressing these facts upon my mind; and I send you brief abstracts of a few of them.

I. Mrs. B., æt. 28; had two children. When I first saw her, she had been suffering severe pain for some hours; but

my arrival frightening her, they ceased. The os uteri was dilated to about the size of a crown-piece, its margins being neither thick nor hard; the vagina well dilated, and lubricated with mucus. I left her, and the pains did not recur for a fortnight; they then became powerful, and the labour terminated in a few hours.

2. Mrs. N., æt. 35; pelvis ordinary size; had five children. When I first saw her, she had had feeble pains for some hours, and these continued of a most trifling character. Os uteri very high up, but little dilated, yet thin; liquor amnii not discharged. Almost immediately after a severe pain or two occurred, and before I could get across the room the child's head was rapidly distending the perineum.

3. Mrs. C., æt. 21, small stature; had one child. Pains had been sharpish, but now feeble, and very infrequent; os uteri very little dilated, and liquor amnii discharged. Two pains completed the dilatation, and expelled the child.

4. Mrs. B., æt. 33; pelvis rather capacious; had three children. Pains very slight; not more severe than they had occasionally been for the last two months. I could but just reach the os uteri; dilatation had not commenced, the margins were thick and hard, and liquor amnii not discharged. Considering that her labour had not commenced, I left her. This irritated her much, and a sharp pain coming on, I was recalled as I went down stairs; and, to my utter surprise, found the os uteri fully dilated, and the child fast entering the world. I explained the case as well as I could to her, but with no avail.

5. Mrs. L., æt. 39; had twelve children. Pains very slight; os uteri very high, very moderately dilated, and possessing a thickish edge. I made up my mind to wait patiently, but was called to the bed-side again in half an hour (the patient since I examined her having scarcely complained at all), and agreeably surprised to find I was just in time to receive the child. She said, for the last half-hour she had felt "her womb opening."

It has been so frequently my lot to see labour completed with such very trifling pain, that I never leave a patient, however little she may have suffered,

without making an examination; and always remain with her, if I find the os uteri thinnish and soft, whether the dilatation be great or not; while, if the margins are thick and hard, I leave her for a few hours, though not always with impunity, as in Case 4; any one exactly similar to which I do not remember to have met with.

I should not have troubled you with this, had I not seen numerous cases where harm resulted from accoucheurs leaving their patients when the labour had made greater progress than the pain felt would lead one to suppose; and much vexation caused by promises of a speedy termination of the case, which some event has frustrated. In all cases the confidence of our patients is a powerful auxiliary, but in none so much so as in midwifery; and it is not by rash promises, but by careful prognosis, we best obtain it.—I am, sir,

Your obedient servant,

JOHN CHATTO,

Memb. Roy. Coll. Surgeons.

ADVANTAGES OF DRAWING TO THE MEDICAL STUDENT.

To the Editor of the Medical Gazette.

SIR,

HAVING always found your pages open for the reception of all observations that could tend to the advancement of medical science, whether in connexion with the studies of the pupil at the hospital, or the researches of the practitioner, I trust that you will not consider the following as unworthy of a place in your journal.

It has long been a matter of regret to me that a knowledge of the art of drawing has not been considered a necessary part of the education of the medical student previous to his coming to the hospital. I will, therefore, as briefly as possible, state my reasons for considering this branch of general education as highly important.

In the first place, the student will find the art of drawing a great assistance to him while pursuing his studies in the dissecting-room. The object which he has in dissecting is to expose,

by means of his scalpel, the different structures of the human body, and to lay bare the relative position of each organ, thus producing, if I may be allowed the expression, certain pictures, which it is his duty to remember. Now, it is unfortunately a fact well known to those who have been long in the habit of attending in the dissecting-room, that a knowledge of anatomy is too soon forgotten, and I believe for this reason—that the simple act of dissecting a part does not necessarily oblige the individual to dwell upon the appearances for any length of time, and the image of it therefore soon fades from his memory, though at the time that he had the subject before him, he believed that nothing could possibly obliterate that image. It seems to me to resemble what often occurs to a man in visiting a picture gallery: he admires a beautiful picture by Claude, reads about it in his catalogue, and at that moment thinks that he can never forget it; but a fortnight afterwards, however, he is surprised that he can hardly recollect even its most prominent features. And why, we might ask, this failure of the memory? Because it required no exertion of the mind to become acquainted with the picture; but had the same individual made a record upon paper of the picture, instead of merely looking at it, and reading about it, he would then, in all probability, have recollected for life; and so would it be with the medical student, if he made sketches of all that he dissected. I am aware that in answer to this illustration of my argument, it may be said that the two cases are not perfectly parallel, inasmuch as the study of anatomy requires considerable exertion of the mind, and that the student ought to assist his memory by diligently reading at the same time that he dissects. The knowledge of anatomy, however, which the surgeon requires in the performance of a difficult operation, is a knowledge which will enable him to bring before his mind's eye, at the time that he is operating, a perfect picture of the relative anatomy of the part, and this knowledge can only be obtained by repeated observation, which observation drawing certainly obliges the student to give. The practice of drawing will very much facilitate the student in acquiring that accuracy of eye and manual dexterity which are so absolutely necessary to the

skillful performance of operations: he would derive another advantage from sketching the different parts that he dissects, namely, that he would then feel the necessity of shewing every structure distinctly, and dissecting each separate organ neatly, which many students will not do when they consider that their dissection is to be thrown away as soon as they have concluded it. I therefore think that if the student had an additional reason for dwelling a longer period over his dissection, that the impression made upon his mind by the appearances would be more firmly fixed.

The advantages to be derived from a knowledge of drawing will be felt almost as much in the study of morbid anatomy, as in that of descriptive: the student, while at the hospital, has a greater opportunity of witnessing morbid appearances than occur in private practice: these appearances are evanescent, and can only be recorded faithfully by drawing, and if he take advantage of the opportunities thus afforded, he will perpetuate his experience at the hospital, and afford himself in after life very gratifying recollections of his industry.

In the study of skin diseases, drawing will add considerably to the ardour and very much facilitate the student in acquiring a knowledge of their distinguishing characters; and if he should at any time visit the Hôpital de St. Louis, at Paris, he will there meet with such a field for his pencil that nothing can express the satisfaction he will then derive from the use of it.

The pupil will find drawing a very agreeable recreation during a long winter's evening, after having finished his more severe studies; and those who know nothing about it on their arrival in town, might, in a few weeks, gain sufficient knowledge of it to add very much to their interest and advantage in the study of their profession.

In the hope that these opinions may accord with those of my professional brethren in general, I trust that some benefit may be obtained by thus calling attention to what appears to me their utility and importance.—I am, sir,

Your obedient servant,
SAMUEL SOLLY.

15, St. Mary Axe, Sept. 2, 1833.

EXTRACTS
FROM THE
PORTFOLIO OF A PHYSICIAN

Practising in London.

No. II.*

1. *Congenital Hypertrophy of the Liver.*

JAMES AMBROSE, three years of age, born of healthy parents, died at the Small-pox Hospital of small-pox, on the 9th Dec. 1826. The pox was not of a bad sort, and I wondered what he died of. The abdomen felt large and full. On dissection, four ounces of water were found in the belly. The liver was ash-coloured, and of enormous size. The thorax was quite healthy.

When the child was three months old, the mother noticed the swelling of the belly, and ascribed it to early weaning, and the habit of sucking its thumb. The child eat heartily, and its general aspect and health were unimpaired up to the attack of small-pox; had no dyspeptic symptoms; had never emaciated. Stools very offensive, but not otherwise unhealthy. The child had never spoken, but was lively. The mother long ago made him a pair of stays to support the belly, and the child would often come to have the strings tightened or loosened. The disease was, in all probability, congenital.

2. *Bugliè on Cantharides.*

The opinions of this author on the application of blisters appear to me to possess infinite merit. He believes that the cantharides are absorbed into the blood, and there often do mischief by reason of a *sharp salt* which they contain, and which has a poisonous quality. Blisters may cause gangrene, especially in gangrenous states of the air. They are dangerous in disorders of the brain attended with ardent fever. Under such circumstances they may bring on convulsions. In all convulsive disorders attended with fever, avoid blistering. Blisters are bad in hot and dry constitutions; where there is great agitation and impetuosity of the blood; wherever fever runs high. Such as have been poxed are liable to suffer from blisters. Be very cautious with them in thin and spare habits. In such, they often cause startings of the tendons. They are

improper in men of an adust or bilious temperament. They sometimes bring on a filthy satyriasis, and bloody urine. They are most dangerous in the summer season. They are hurtful in cases attended with delirium.

On the other hand, blisters are very good in a gross and viscid disposition of blood, tending to coagulation and stagnation. In fevers accompanied with a very low pulse, coldness in the extreme parts, and proneness to sleep — in the winter season — in moist constitutions, and fat habits, blisters are surprisingly beneficial. Oribasius first wrote on them. The Arabian physicians employed them largely in soporose and cold disorders. They are useful in pleurisy, after the fifth day. It is absurd to suppose that blisters applied in malignant fevers can draw out the venom. In diseases of the eyes and face, blisters applied to the nape of the neck are very serviceable.

Honey of roses is a good application to the ulcers left by blisters. Frankincense powder (*Abietis resina*) strewed upon an ulcerating blistered surface, does good. Lint dipped in alum water is also a good application; *but when the body is very foul, even these do but little service.*

Exhorts physicians to try cantharides in chronic obstructions of the viscera, seeing that such disorders often arise from a gross, coagulated, and stagnating blood, or from ropy disorders of the other humours.

[At St. George's Hospital, Dr. Seymour is now employing the tincture of cantharides in certain cases of dropsy with much benefit.]

In chronic coughs, and catarrhs accompanied with viscid expectoration, blisters to the neck are particularly serviceable.

3. *Excessive Intoxication.*

The following cases of excessive intoxication were communicated to me by my pupil (Mr. Hale) as having occurred under his own observation (June 18, 1823):—

Two sailors were brought on board ship, after drinking for two days. They continued in a state approaching to coma for five days, and ultimately recovered perfectly. They had insensibility, a kind of locked jaw, preventing all food or medicine from being taken, and a small but rather excited pulse; not very

* No. I. appeared in our 2d volume, page 632.

different, however, from the pulse of health.

Such cases are not uncommon in the navy, particularly after a ship has been paid off. The rule of practice is never to bleed them. Purge them; if possible, by internal medicines; if not, by enemata. Give them, occasionally, a table-spoonful of grog. The singularity consists in the great length of time that these symptoms will last, and the brain ultimately recover its functions perfectly.

4. *Influence of Manner upon a Physician's Success.*

I do not remember to have ever seen the following passage quoted, but it is too good to remain hid upon a dusty shelf. If any of our fashionable and consulting physicians should have overlooked the passage—forget it, they could not—they will thank me for thus bringing it before them. It would lose all its spirit by any attempt at translation.

“In ægris curandis præstare maximopere debet medius, ut quæcumque remedia aut præcepta (curationem spectantia) ægroto præponit, ea tali arte et intrepida dicendi libertate proponat, qua illum ad patientiam et tranquillitatem componere, et ad summam medicamentis præbendam fidem, hortari valeat. Medicus namque in sermone potens, et artium suadendi peritissimus, tantam vim, dicendi facultate, medicamentis suis adstruit, et tantam doctrinæ suæ fidem in ægro excitat, ut interdum vel abjectissimis remediis difficiles morbos superaverit; quod medici doctiores, sed in dicendo languidi, molles, ac pene emortui, nobilioribus pharmacis præstare non potuerunt. Hinc etiam fit, ut diversi medici, ab iisdem remediis, non eodem experiantur effectus, sed alii faustos, alii infaustos; siquidem alii fidem et spem in ægro excitare optime norunt, dum alii, inefficaces et pene clanguidi, illius imaginationem neequidem attingunt.”—*Baglivi*, lib. i. cap. 14.

ON UREA—NITRO-STEARIC ACID, &c. &c.

To the Editor of the Medical Gazette.

SIR,
WE consider ourselves called upon (for the last time, we hope) to make some

reply to the reclamation contained in your journal of Saturday last. The commencing paragraph is a mere disagreement about words, and may therefore be passed over without further notice. Your correspondent (if we interpret him rightly) expressly states, that he never doubted that the presence of urea in the blood was the cause of the peculiar symptoms manifested in the disease in question; and he seems to intimate, that those peculiar symptoms are affections of the head in particular. Now although we are quite aware that the serous membranes of the brain, as well as lungs, are not unfrequently complicated, still we can prove that such derangements are not depending upon the existence of urea in the circulating fluid (which he asserts to be the case), inasmuch as one of the specimens of blood examined by us was obtained from a patient in whom well-marked cerebral disturbance was more than once set up during the existence of anasarca with coagulable urine, and yet not a trace of urea could be detected in the blood.

We regret that the term *nitro-stearic acid* is not consonant with his ideas of chemical nomenclature; there is, however, nothing novel, and we think nothing objectionable, in it, countenanced and adopted as it is by Berzelius himself, from the fact of his naming certain compounds of organic matter and nitric acid in a similar manner, as, for example, the nitro-leucic and nitro-saccharic acids; and we would observe, that the title nitro-stearic no more implies the presence of stearic acid, than nitro-leucic does that of leucic acid, even if such a substance exist, but simply expresses the fact that there is a binary compound formed by nitric acid and *stearine*, similar to that of nitric acid and leucine, or the same acid and sugar of gelatin.

We shall now shew that the employment of water instead of alcohol, in the first part of these experiments, is not sufficient to preclude various sources of fallacy, although it may effectually prevent any appreciable quantity of fatty matter from being taken up; and conclude by stating in what manner every such source of fallacy may be avoided. It is a well-known fact, that if nitric acid be added to common salt, chlorine with dentoxide of nitrogen is evolved, and nitrate of soda formed, which, like the same salt of potass, crystallizes in prisms. If one of these crystals be

placed on platinum foil, and held over the flame of a spirit-lamp, it fuses, and appears to be dissipated whilst the foil is hot, but upon cooling it will be found to have spread over the surface of the latter, forming an exceedingly thin, opaque incrustation; if, on the contrary, the same salt be impregnated with a little animal extract, or fatty matter, it fuses, scintillates, and is entirely dissipated, owing to the decomposed organic matter and nitric acid forming gases, which, at a pretty high temperature, carry off in their vapour the minute quantity of soda set free. Now when nitric acid is added to the concentrated aqueous or alcoholic solution obtained from coagulated serum, nitrate of soda is in every case formed, more or less combined with animal matter, and consequently undergoing the same changes by heat as those just detailed; and besides all this, when alcohol is employed, the fatty matter, as before noticed, becomes an additional source of error.

The ammoniacal odour evolved by boiling such crystals in potass cannot be considered as characteristic of urea, because most animal principles are similarly situated.

It is quite clear, therefore, that none of the tests above enumerated can be safely employed for detecting urea in the blood; but the following observations will, we trust, clear up the difficulty.

The substance obtained by the action of nitric acid on the watery or alcoholic extract ought not to assume the form of brittle transparent crystals, but that of soft plates, having a beautiful and highly-characteristic silky lustre when viewed by reflected light, undergoing perfect solution in a very small quantity of cold water, and in a somewhat larger quantity of cold alcohol; it should be converted, at a temperature below that which is necessary for charring it, into nitrate and carbonate of ammonia. Although there are other properties besides those enumerated possessed by nitrate of urea, these will be found amply sufficient to distinguish it from every other animal substance found in the blood.

1st, Its solubility in small quantities of cold water and alcohol will readily distinguish it either from stearine, or *nitro-stearic acid*, neither of these last being soluble in small quantities of water.

2dly, Its solubility in cold alcohol

will at once distinguish it from the nitrate of soda or potass.

3dly and lastly, Its forming nitrate and carbonate of ammonia, at a temperature below its point of charring, will distinguish it from the peculiar animal matter soluble in water.

We have prolonged our remarks beyond the limits we had first intended to have confined them within, but we trust the importance of the subject will be deemed a sufficient excuse. There are certain obvious physiological facts which would lead us to reject the idea of urea being present in the blood, which we cannot enter upon at present.

By inserting these remarks you will much oblige

Your obedient servants,
R. H. BRETT.
GOLDING BIRD.

Guy's Hospital, Sept. 11, 1833.

MEDICAL GAZETTE.

Saturday, September 14, 1833.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

IRISH SPECIMEN OF MEDICAL REFORM.

WE endeavoured last week to shew, that however much the present parliament may feel that they are called upon to listen to demands for justice, and to inquire into alleged abuses in the medical as well as other professions, yet that it must rest with us as a body, by combined and well-directed exertions, to keep ourselves and our affairs in their memories; else shall our poor concerns be swallowed up in the vortex, and the cause be lost among the hundred and thirty-four "notices," of which we hear so much. We fear the evil is unavoidable; but too much is evidently left by our legislators to the effects of intrigue and individual interest. This is the point we were so anxious to enforce in our former article, in order that, as such is the case, those among our brethren who

have these things at heart might avail themselves, during the recess, of the opportunities which offer to make the members of parliament a little better acquainted than they are with various matters touching the polity of the medical profession. Unless this be done, the process of their enlightenment will be very slow, and the general good, for an indefinite period, still be sacrificed to private interests. By some this will be done from ignorance, and by others from more censurable motives.

To come to particulars, however, we shall illustrate what we mean by an example in point. To those who do not appreciate the effect produced on the opinions of "honourable" members by the expressed wishes of a few busy and influential persons among their constituents, the fate of measures must often appear most capricious and inexplicable. To some, for instance, it no doubt appears very odd that the parliament did not choose to legislate respecting the Apothecaries' Act, notwithstanding all the petitions that were presented on the subject; but postponed any enactment, because it was proposed to have a committee on the general subject of medical education and medical concerns during the next session, to which of course it would be proper to refer all professional questions, previously to legislation thereon; and yet, that after having assigned this very plausible reason for "non-intervention," it has pleased the same parliament to pass the Irish Grand Jury Bill, containing a clause fraught with injustice to the surgeons of Ireland, and against which numerous petitions were presented by the parties aggrieved. The Clause in question (75) enacts, that the Grand Jury may present for the sum of 100*l.* every year, to be given to the surgeon of any County Infirmary, *provided he be a member of the Dublin College of Surgeons!* Now this has been very truly represented in numerous me-

morials, as well as by the medical authorities in this country, as being an enactment of a nature the most invidious, illiberal, and unjust, to those Irish gentlemen who have been prevented, by the Bye-laws of the Dublin College, from becoming members of that body. There are many such, who have been born, bred, and educated in Ireland—have paid their fees for lectures and for attending hospital practice (aye, and to those very gentlemen, members of the Dublin College, in whose favour the exclusion is granted,)—but who have been obliged to resort to England or to Scotland for their diplomas, because, forsooth, they had not paid an enormous apprenticeship fee to one of the Irish body of exclusives. For be it known to such of our readers as knew it not before, and be it kept in mind by all, as a fit piece of information to be communicated to the M. P. in their neighbourhood, that no man can become a member of the Dublin College unless he has previously been apprenticed to one of that body: or in other words the question is one of money, and of money only. By this unjust and exclusive monopoly, the County Infirmaries of Ireland have become the property of the Dublin College of Surgeons, and the present *modest* act is intended to perpetuate this profitable appropriation. Nor are the grounds of defence less fallacious than the principle is obnoxious: one of the pretexts originally set up, was, that the members of the Dublin College had no right to practise in England; and this flimsy and false excuse was even mentioned in parliament. But all the world—out of St. Stephen's Chapel—know that any man who chooses to call himself a surgeon may practise as such in all parts of England—witness Mr. St. John Long the Irish painter, and others. The legislature has given no protection nor security to the poor or to the wealthier

part of the public of this country against the effects of ignorance or empiricism; for it has not insisted on surgeons giving proof of their competency previously to undertaking to practise the healing art, but suffers them to tamper with the health, and limbs, and lives of his Majesty's subjects at their pleasure, subject only to legal retribution in the event of inflicting some great and palpable injury. Another ground of defence has been, that English surgeons are not entitled to Irish money. This is another fallacy, or rather it is a wilful deception; for all the petitioners, all who are thus aggrieved, are Irishmen—most of them educated in the sister kingdom, and apprenticed to surgeons in Ireland—men probably of talents equal to those of any members of the Dublin College.

Dr. Macartney, the Professor of Anatomy and Surgery in Trinity College, Dublin—a man of acquirements and celebrity, certainly not surpassed by those of any surgeon in Ireland—is, although an Irishman, incompetent to hold the appointment of surgeon to a County Infirmary!—And why is the distinguished Professor of Surgery in Dublin excluded from being an hospital surgeon; or rather, why is the public deprived of his services? Why—because he is a member of the first Academy of Surgery in the British dominions—the London College—and, by virtue of the same diploma which confers on him this distinction, his pupils and apprentices are equally disqualified from those privileges to which, in common sense, and common justice, and common decency, they are entitled. Hitherto, however, the Dispensaries and the Fever Hospitals have been open to those Irish gentlemen who are members of the London or Edinburgh Colleges; but the Bill introduced in the House of Lords, by Lord Westmeath, to *regulate* (!) Infirmaries and Dispensaries,

has not only multiplied the number of Infirmaries, for the benefit of the members of the Dublin College, but has actually shut out all others from the Dispensaries also. Now all this was done after it had been resolved that a general inquiry into the medical profession should take place next session; and yet no senator—no minister of the crown—no independent member of either house—was honest or bold enough to propose that this unjust Bill should be postponed, and the subject referred to the same Committee that is destined to decide on other similar questions, and the appointment of which was deemed a valid reason for postponing matters more urgent. We believe that the London College of Surgeons exerted themselves to the utmost, both officially and privately, with the ministers and with other members of both Houses: but the influence of the Irish members was found to be paramount. And yet they must be labouring under error;—we are convinced they cannot be aware that the injustice is inflicted solely on their own countrymen.

However this may be, it is notorious that the measure was carried by the instrumentality of the Irish members, who had been crammed by the interested parties—who had been ear-wigged by deputations from Dublin—who had been made to believe that they were protecting “poor Ireland” against some small portion of the oppressions of England, by keeping all the hospitals and all the money for the members of their own College; not knowing, or in their natural zeal not considering, that they were supporting a monopoly in favour of one portion of their countrymen to the injury of their not less deserving brethren, and that the persons whom they have so cleverly kept out of their fair advantages and emoluments, are, in ninety-nine cases in the hundred, Irishmen—born, educated, and practising in the same country as their oppressors.

The College of Surgeons in London, as we have mentioned, exerted their influence; but the Irish members were red-hot upon the subject, and the government would not interfere: it was deemed politic to let them have something their own way, and probably the ministers were right well pleased to gratify them at so cheap a rate.

The above, then, is the kind of parliamentary blunder, with regard to our profession, which we are desirous to provide against. It resulted in the ignorance of the Irish members, and the want of any connexion between them and their medical countrymen as a body. Let the profession here be more on the alert, that we may be spared the infliction of similar specimens of legislation; let our members of parliament be made aware that English surgeons are excluded from the fair practice of their profession in Ireland, while Irish surgeons are freely admitted in England to full and equal privileges; and then we doubt not but that this stupid enactment will be reversed, and our Irish neighbours, in being taught what is just to others, will only be made to do compulsory justice to themselves.

ALDERSGATE-STREET DISPENSARY.

RESIGNATION OF HIS ROYAL HIGHNESS
THE DUKE OF SUSSEX, PRESIDENT,

AND OF

ALL THE MEDICAL OFFICERS.

WE beg to call attention to the important details which follow; the facts speak for themselves. At present we have only time and space to express our unqualified approbation of the step taken by the medical men, and to intimate our hope and belief that no respectable members of our profession will be found to succeed them. The system of allowing votes to be made at any time after a vacancy has been declared, is tantamount to offering it for sale to the highest bidder.

Meeting at which the Sale of the Medical Appointments in Aldersgate-street Dispensary was determined on.

On Wednesday last, a general meeting of governors of the Aldersgate-Street Dispensary was held at the institution, (the Right Honourable the Lord Mayor in the chair,) for the purpose of considering the revised laws and regulations of the society, as recommended by the committee, more especially those relating to the mode of electing the officers of the establishment.

According to the 23d rule of the society, "no person can vote at any election who has not been a governor for six months previous to the day of election." This regulation was adopted about seven years ago, with a view to prevent a recurrence of pecuniary contests between candidates for the offices of physician or surgeon to the institution. By the original law of the society, governors were entitled to vote immediately on payment of their subscriptions, and many instances occurred of votes, real or fictitious, being created in considerable numbers, for the purpose of carrying the election of particular candidates. At the last general quarterly meeting it was proposed, in pursuance of a report of the sub-committee, to recur to the old system, and permit governors of three days' standing to vote at elections; but the resolution was negatived by a majority of 56 to 53. The resolution has since been slightly modified by the committee, and was on Wednesday last submitted to a general meeting in the following shape:—"That no annual governor shall be entitled to vote by proxy who shall not have paid his or her subscription two months previously to the day of election; nor shall any such governor be entitled to vote personally who shall not have paid his or her subscription seven days previously thereto."

The secretary having read the minutes of preceding meetings, and the revised laws and orders recommended by the committee for adoption—after some irrelevant discussion—it was moved and seconded that the minutes be confirmed.

DR. CLUTTERBUCK rose for the purpose of moving as an amendment, that the minutes now read be confirmed, with the exception of the report of the sub-committee on the revision of the laws of the institution, and that such report be referred back to the sub-committee for reconsideration, and that one physician and one surgeon be added as members to such committee. He wished to observe, that at a meeting not long since specially summoned for the purpose of considering the subject, the question had been decided against an alteration in the existing rule of voting. That being the case, it did appear to the medi-

cal officers extraordinary that the committee should within a week of the decision referred to again agitate the question. It was true that the committee professed to adopt what they called a middle course, but the only essential difference between the present proposition and that which was formerly negatived, consisted in the substitution of "seven days" for "three days." This alteration did not appear to the medical officers to involve the adoption of a middle course; far from it; it enabled governors, made such for a particular purpose, to exercise the right of voting, and still left the offices of the institution open to be bought and sold. Under such a regulation, the medical offices would be attainable by money only, a secondary regard being paid to the character and talents of the candidates. The present medical officers had no interest in the question: the mode of conducting future elections could not affect them, however it might affect the respectability of the institution. To this latter consideration he and his brethren had not been insensible. They felt that in an institution such as this, which depended on public opinion for support, respectability and prosperity were nearly, if not altogether, convertible terms; and therefore, with a view to maintain the character of the establishment, and the respectability of the medical profession, in the officers who were to come after them, they felt bound to discourage the proposed alteration in the laws of the society.

The REV. J. RUSSELL, thinking the proposition which had been just made the wisest that the governors could adopt, heartily seconded the amendment.

MR. SALMON said, that before such a proposition as the present was made, the committee should have been fully satisfied that it was necessary, and that the alteration would benefit the charity. He denied the necessity of the alteration, and referred to the treasurer's books in confirmation of what he said. The committee in their circular to the governors spoke of "the gradual diminution of the funds." He denied the fact, and was prepared to prove that the charity was now in a better state than it had ever been in before. In 1808, the annual funds did not exceed 309*l.*; at present they amounted to 1000*l.* The funds were fully adequate to the purposes of the institution, but even if any deficiency existed in that respect, he denied that the proposed alteration would afford the best mode of supporting the charity.

MR. HERRING argued that the change would promote the pecuniary interests of the institution, and went into various numerical statements to show that the average annual number of new governors had been

considerably greater under the original than under the new system.

MR. COULSON said, he understood that one principle for which the committee contended was, that the medical men should not be enabled to nominate their successors. To that principle he and his colleagues fully assented, and were only anxious to establish this other principle—namely, that no man of bad character or inadequate attainments should have an opportunity of purchasing his way into the institution. Both principles were right, and he thought that by a slight concession on either side, matters might be satisfactorily arranged.

The LORD MAYOR regretted that the very respectable professional gentlemen had referred to the possibility of their resignation, because it had been looked on as a threat.

MR. COULSON observed that neither by his colleagues nor himself had resignation been put forward as a threat, but because they conceived a principle to be involved in the proposed law of election, which, if carried, would militate so strongly against the character of the institution, and the respectability of the profession, as to render it impossible for them to remain.

A division then took place, when the numbers were—

For the original question . . .	85
Against it	46
<hr/>	
Majority for the confirmation of } the minutes of the Committee }	39

MR. MILLS moved "that the thanks of this meeting are due, and are hereby given, to the medical officers, and that they be requested to continue their valuable services to the institution." He trusted that the motion would be carried in such a manner as to convey to those gentlemen the high sense entertained of their zeal and ability; and he ventured to hope, notwithstanding what had passed, that they might be prevailed upon to reconsider and abandon their purpose of resigning.

MR. SACL seconded the resolution, which was then put, and carried unanimously.

DR. CLUTTERBUCK expressed the gratification he felt at the resolution just passed; but having made a stand, in concert with his medical brethren, on a principle which they considered of importance to their own characters, to the medical profession, and to charitable institutions themselves, he found himself utterly unable, with satisfaction to himself or with benefit to the institution, to continue his services, now that a principle so contrary to his own had been established for the guidance and ma-

nagement of the society. He regretted the necessity which separated him from an institution to which he had been so long attached; but, under existing circumstances, he found it impossible to continue connected with it. He had only to add, that he should be happy to see his Dispensary patients at his own house, till his successor should be appointed.

DR. LAMBE also tendered his resignation.

DR. ROBERTS felt bound to adopt the course pursued by his medical brethren. Looking at every thing that had occurred, he did not know that he could take leave of the institution better than in the words of Cato:—

“When vice prevails and impious men bear sway,
The post of honour is a private station.”

MR. SALMON felt, considering the situation in which he was placed, with a probability of differences of opinion arising between the committee and the medical officers, that he could not longer do his duty to the institution satisfactorily to himself. Such being the case, for the sake of the institution, of his own character, and with a view to uphold the dignity of the profession, he was bound to retire from the situation which he held in the establishment.

MR. COULSON also resigned, being unable to remain in office without a sacrifice of respectability and character to which he could not submit.

[Each of the medical officers stated his intention of receiving the Dispensary patients at his private residence, till the appointment of his successor.]

DR. BIRKBECK, believing the principle now established calculated to prove injurious to the institution, must follow the example of his colleagues. The law of election now rescinded was calculated, if not immediately to increase the prosperity, at least to establish the character and respectability of an institution such as this; and ultimately the prosperity of that institution must be the greatest, which possessed the greatest respectability. He regretted the termination of his connexion with an institution so long established and valuable, and which he had in less prosperous times struggled hard to save from insolvency. To take leave of the society was exceedingly painful to him, more especially after having witnessed symptoms of certain feelings during a part of the debate of which he wished to say nothing, except that he thought it would have been better if they had not been expressed. He wished the institution every prosperity, and hoped that still as hitherto it might preserve its reputation and its character for utility undiminished. He

had received a letter from the Duke of Sussex, President of the institution, in which his Royal Highness expressed more strongly than it might be agreeable to every one to hear, his feeling on the subject that had engaged the attention of the meeting that day. He would read a sentence or two of the Royal Duke's communication. Dr. Birkbeck then read an extract from the Duke's letter, which stated, that should the professional gentlemen think it necessary to retire, he also would withdraw himself from his office of President of the charity. He had supported the institution, inasmuch as the character and respectability of those professional gentlemen were known to him, on which knowledge he grounded his expectations and belief of its utility. Having quoted these portions of the Royal Duke's letter, it only remained for him, on the part of his Royal Highness, to tender his resignation of the office of President.

Thanks having been voted to the Lord Mayor, the meeting adjourned.

ST. GEORGE'S HOSPITAL.

CLINICAL REMARKS ON

The Operation for Necrosis of the Femur—Hæmorrhage—Ligature of the Femoral Artery—Amputation.

BY MR. CÆSAR HAWKINS.

[Concluded from page 751.]

WHEN a portion of dead bone is firmly locked in, and is not broken down by absorption, from being too hard, or from the living part around it being sufficiently vascular, an operation becomes necessary by which it may be extracted. It might, indeed, very often be left with safety to the operations of nature; but many years are often required for this purpose, during the whole of which there is more or less inconvenience to the patient, with a troublesome discharging abscess, or numerous sinuses. Nor, indeed, is the patient's condition always without danger, from the constant drain and irritation, or from numerous small abscesses which form from time to time. All this inconvenience may be remedied by an operation—painful, indeed, but not often attended with risk; and several years of suffering may be saved by thus assisting in getting rid of the sequestra. For instance, an old soldier was under my care in the hospital, whom I operated on twice for strangulated hernia: after the first operation, he complained of a constant discharge from one side of the nates,

which materially impaired his health, and which came from a sinus that led to a dead piece of bone on the back of the ilium. He had been wounded nineteen years before, at the siege of Badajos, by a musket-ball, which had pierced the abdomen in front, and gone through the ala of the ilium. By an incision through the glutei muscles, I removed a piece of bone the size of a half-crown, and scraped away a little carious and living bone around, and it directly healed, and has continued sound ever since. If, then, so many years were here insufficient to get rid of the dead bone, even from the ilium, where it was unconfined, it is not surprising that the same operation is often required in the long bones, where a quantity of new hard bone surrounds the sequestrum.

Such, then, was the case in Chandler, after three years and a half. The lower third of his thigh was of an immense size, from very hard new bone, in which there was one opening of a small size leading into a considerable cavity, enclosed completely by new bone, except at this orifice, which was situated in the part I before spoke to you of, near the lower end of the vastus internus, and just above the internal condyle of the femur. In this cavity was felt a considerable piece of dead bone insulated, but apparently fixed at the two ends by the new bone. The soft parts were adherent to the new bone round the edges of the opening, while the muscles were in a natural state elsewhere.

The operation for necrosis must vary according to the particular circumstances of each case. What I did for Chandler, on the 13th of December, was this:—I first divided the skin above and below the opening, and separated it from its adhesion to the new bone; and with a trephine I removed two pieces of the new bone, so as to expose a good deal of the old and dead portion which was loose; but the ends being broad it could not be extracted without being divided into two portions, or the opening in the new bone being made much larger. I first tried to divide the dead piece with a small key-hole saw, directing the edge of the saw forwards, so that the back of the saw was towards the popliteal artery, which was of course very near the bone, but by this means perfectly safe. The bone was, however, too hard to be cut through in this manner without great difficulty. I placed, therefore, a small trephine upon the edge of the centre of the dead piece, and thus easily divided it into two portions, which were readily extracted through the opening. When joined, the sequestrum was about four inches long, and between two and three inches broad; being the back part of the bone, where it is flattened and expanded into the condyloid part. The wound was

dressed with a piece of lint in the cavity of the bone, and, as nothing but skin was divided, there was no vessel that required tying.

The operation for necrosis is always a painful one, and the wound almost always becomes more or less foul and sloughy; in this case, however, when the lint was removed on the 18th, the wound was very tolerably healthy, and was beginning to granulate well; so that there seemed no reason to anticipate, from the state of the parts, what took place the next day.

December 19th, while exerting himself in bed, there took place sudden hæmorrhage from the wound, and the house-surgeon (Mr. Cooper), who was not far from the ward at the time, was immediately called, and came to him almost directly. He supposed that not less than three pints of arterial blood had already escaped, and that nearly a pint more was lost before he could stop it by pressure, and then apply a tourniquet. I arrived at the hospital in almost half an hour, at which time he was quite exhausted, and bathed in cold perspiration, and with scarcely any pulse to be felt even in the femoral artery; and this not from alarm, for nothing can have been greater than his firmness and composure during all the severe operations he has gone through, and which certainly have been more than the usual share of one person; but his state was evidently owing to the quantity and suddenness of the bleeding.

The question then was, what was the source of this hæmorrhage, and what was to be done for him; as the repetition of the bleeding, even in small quantity, must have been fatal.

The bleeding was clearly not from the anastomosing vessel which I before spoke to you about, but deep from the bottom of the wound—from some vessel, or vessels, opened by ulceration or by sloughing, in consequence of the operation. Mr. Cooper described the bleeding as being so great that a stream of several inches high issued from the wound (large as it was), and as being entirely arterial. As, then, the wound was not sloughing extensively, so as to open at once a great number of arteries, it seemed scarcely doubtful that the bleeding was from the popliteal artery, which, although untouched by the instruments, might yet have been injured by the end of the sequestrum, close as it lay to it in the wound, so as to bleed when opened by ulceration a few days afterwards. This, then, was the decided impression of all the gentlemen who happened to witness the hæmorrhage; and from this account of the quantity of blood lost during the short time that it lasted, and the state in which I found him, I entertained no doubt of its correctness.

Upon consideration of the following important questions, I determined at once to tie the femoral artery, which was directly done, and, as it proved, with perfect success.

1st. There is no doubt that, upon the first discovery of the freedom of anastomosis, when even the largest arteries were tied by some of our own most distinguished surgeons, the surgeons of this country were induced to be too sanguine as to the resources of nature after such operations, and were induced to lose sight of the different circumstances in which the circulation is found when a large vessel is tied in a case of aneurism, or of a wounded or ulcerated artery. It is to the large scale on which such cases were seen by our army surgeons, of whom no one has insisted more upon this point than Mr. Guthrie, (whose recent work upon this subject I recommend to your study,) that we are indebted for a more correct knowledge of the fact that there is a much greater chance of failure of the circulation, and consequently of mortification, where an artery is tied suddenly in a case of wound than in a case of aneurism, where the capillary vessels have already had time to become somewhat enlarged, by the impediment to the current of blood through the main trunk, produced by the disease. Certainly, from several instances which I have seen, I am inclined to believe with them, that if the main artery and vein are both obstructed by a ligature, or in any other sudden way, the death of the parts below is almost inevitable. But when an artery alone is tied, I cannot but think that the danger has been somewhat exaggerated, and that the dread of mortification has arisen from so many of the instances adduced having been cases of gunshot wounds, or other severe injury, in which the blood driven into the soft parts, or the swelling necessarily following the wound, has contributed very much to the fatal result by pressure upon the neighbouring small vessels. Where there has been injury of this kind, no doubt you will very often see the occurrence of mortification; but in cases of simple obstruction I cannot think that it is often to be looked for, though doubtless somewhat more frequently than after the operation for aneurism. In this patient, you will have observed that although the femoral artery was thus suddenly tied, and there was a considerable mass of disease below the ligature, not only was there no coldness of the limb, but there was not even the increased temperature of the surface which commonly attends the ligature of this vessel a short time afterwards, even in aneurism, in consequence of the altered condition of the capillary circulation: the sensibility and temperature of the limb were

throughout exactly the same as in the other leg.

2dly. Another point to be considered, is the frequent occurrence of secondary hæmorrhage in cases of wounded or ulcerated arteries, upon the return of the circulation after the vessel has been tied at a distance from the bleeding point, either from the artery between the ligature and the wound, or from the part of the artery below the wound. No doubt you will be correct, in cases of wounded artery, if the wound is considerable, in cutting down upon the injured part, and placing a ligature both above and below the wound, wherever this is practicable. So, also, where there is a simple slough at the side of an artery, as by a gun-shot wound, this would doubtless be the best operation, if it can be done without difficulty.

But I very much question the propriety of this operation in cases where the vessel has been opened by a sloughing or phagedenic ulcer; in which it is difficult to know what vessel has been opened, or whereabouts the orifice may be, if we think we know, as in this case, what particular vessel is ulcerated; in which cases the wound has to be opened and enlarged in a painful and irritable condition, with almost always considerable difficulty in finding and securing the vessel in the midst of a quantity of sloughs and coagula. In such cases as these, in which mischief is progressively going on (in such a wound as Chandler's, for instance) after an operation, or in a sloughing wound after the operation for aneurism, or in a sloughing stump—in all of which cases secondary hæmorrhage is frequent—I cannot but think that the chances of a return of bleeding from the wound in a few days, when the sloughing or ulceration has again reached the bleeding vessel, is greater than if we leave the wound itself quiet, while the patient's system is at the same time less excited and irritated by an easier and simpler operation upon a healthy part of the artery, at a little distance from the wound. Sometimes, indeed, when the system is very wrong, I have seen the same action established in the wound made to secure the artery. A man, for instance, had the usual operation for popliteal aneurism performed, and secondary hæmorrhage occurring a few weeks afterwards from the wound (which communicated with the sac of the aneurism), the femoral artery was tied by Mr. Brodie above the former incision. There was no return of bleeding from the former wound—which is the point I am contending for—but, six weeks after this, hæmorrhage took place from this second wound; and the bleeding being several times renewed, the common femoral artery was now tied. Again, the ope-

ration was completely successful as to the point at issue: there was no return of bleeding from below, but exactly at the same period after this operation as after the former—viz. six weeks—hæmorrhage took place from the last incision, and ultimately carried off the patient. Again: you will observe that if, after the vessel has been tied above the bleeding point, there should be a return of bleeding, it is generally slighter than before, and more easily controlled by pressure; and after all, if you do fail, you have the same power which you had at first of searching for the ulcerated artery in the wound itself. Much more frequently, however, I believe the operation will be wholly successful, as in our present patient, and as in the case which I have just mentioned of Mr. Brodie's. Let me remind you too again, of the patient I before alluded to (Mr. Babington's), with the same disease as Chandler, in whom alarming hæmorrhage took place, probably from the anastomosing vessel. In this case the artery was several times secured by ligature in the wound, but each time the bleeding returned as soon as the vessel was again opened by ulceration. Then the femoral artery was tied, and there was no subsequent return of hæmorrhage.

Having, then, performed this operation, before the circulation has again become active enough to reproduce the bleeding, the object, of course, must be to produce a new and healthy action in the sloughy and phagedenic ulcer which has caused the hæmorrhage, by appropriate local and constitutional means.

I have nothing particular to say with regard to the tying of the femoral artery, which was done in the upper-third of its course, in the usual way. On the following day (December 20th) he still remained very low and feeble from the hæmorrhage, but had passed a comfortable night.

December 23d.—A little piece of lint, which I generally place in the wound by the side of the ligature, was withdrawn, and which was useful in this case; for while the greater part of the incision had united by the first intention, the centre was rather foul and suppurating, probably from the pressure of the tourniquet, which had been applied just where I tied the artery. He had now some headache and fever, from the irritation of the lower wound, which was full of clots of blood, and was now beginning to suppurate extensively.

24th.—Fever nearly gone.

29th, the tenth day, the ligature came away.

10th January.—Incision almost healed. Wound below healthy; and from it I withdrew a considerable fragment of dead bone,

and several more small pieces were taken away subsequently. From this time, the wound got gradually better, and was contracted to a very small opening, so that he was walking about again without inconvenience.

2d March.—Constant sickness, with febrile disturbance, for which some calomel and antimony, with saline mixture, were given; and the edges of the opening looked unhealthy.

4th.—Sickness continued, with diarrhoea: relieved by small doses of calomel, and antimony, and opium.

5th.—Profuse perspiration and great anxiety. Wound sloughing rapidly, with the peculiar appearance of hospital gangrene. Calomel and opium, with a little wine, were given; and chlorine solution and nitric acid applied to the wound, which on the 9th had spread to a considerable size.

10th.—System better; sloughing phagedena apparently inclined to stop.

15th.—Wound decidedly cleaner, and the sloughing stopped.

I shall not detain you long at present in speaking of the peculiar circular phagedenic sore, called hospital gangrene, which indeed we seldom see in civil hospitals in an aggravated form, and which is also scarcely ever fatal. In military hospitals, however, it is occasionally seen in the most destructive form, and all agree that it is then both contagious (by means of sponges and dressings) and infectious. A very remarkable instance of its propagation by infection is told in a French hospital, at Leyden, in 1798, the wounded being in two rooms one above the other. The disease prevailing in the lower room, an opening was made in the ceiling and through the floor of the upper room, the consequence of which was, that in thirty hours it had become general in the upper room, the soldiers in which had previously been free from it, the first cases being in the beds nearest to this injudiciously made hole, and thence spreading to the others. With us, however, it never seems to be propagated in these ways, though there will now and then occur several instances of the disease in different parts of the hospital: for instance, you have seen very recently two cases of it in patients whose toe I removed.

In Chandler, the exciting cause seemed to be a disturbance of the functions of the bowels and stomach; and constipation, or alternate constipation and purging, very often appear to produce the disease: and the reason, no doubt, of our now and then having several cases at once, is the occurrence of this disturbance from peculiarity in the state of the atmosphere; in the same manner as the occasional prevalence of erysipelas as an epidemic is often traceable

to similar changes in the barometer, or in the moisture of the air.

As soon, then, as you alter this condition of the bowels and digestive organs, the sloughing ceases: in Chandler, this was done by the influence of calomel and opium, with once or twice a rhubarb or senna purgative. But at the same time, in general, a nourishing diet is required, with a little wine or spirit; and the use of ammonia, with camphor or opium, followed by bark, as soon as the stomach bears it. Locally, a cold Goulard poultice, or hemlock, or stale beer, or Port-wine poultice, but more frequently solution of chlorine, or of nitric acid, will procure a more healthy action in the ulcers.

Under this treatment, then, the sloughing phagedena in Chandler stopped, and the system improved; the sloughs were also gradually coming away, but now the ulceration which detached the sloughs produced a fresh danger.

18th.—A few small clots of blood were observed in the dressings of the wound, to which oil of turpentine was then applied repeatedly.

20th.—Under this dressing the wound looked gradually better, and he was improved in health.

21st.—Last night, bleeding to the amount of about ten ounces took place, by which he was a good deal exhausted.

23d.—No fresh bleeding; wound better; decoction of bark and tincture of myrrh applied.

25th.—The house-surgeon, in dressing the wound, observed that there had again been some slight bleeding, and soon afterwards arterial hæmorrhage to a great extent took place, which was controlled for a time by a tourniquet. Mr. Keate, who was in the hospital, being called to him, enlarged the wound, but the exact source of the bleeding did not appear, though his fingers controlled it, when pressed upon the situation of the femoral artery. While he was thus engaged with Mr. Brodie, I arrived at the hospital, and considering his exhausted condition, and the impossibility of his surviving a return of bleeding, together with the large and foul wound which had now been formed by the gangrenous ulceration, and the diseased condition of the femur, we agreed that amputation was the best thing that could be done for him. This operation I therefore performed immediately, below where the femoral artery had been tied, and partly across the incision which had just been made, but above the sloughy part of the wound.

We were now curious to ascertain the source of the present hæmorrhage, as well as the state of the popliteal artery from which the bleeding was believed to have come about three months before, and which

it was thought might again have been opened by ulceration in another place. It appeared, however, that the bleeding was not from the trunk of the artery, but from several branches both of arteries and veins, the mouths of which were quite open on the surface of the wound, chiefly at the upper part, where they arose from the femoral vessels, just before the perforation of the sheath of the triceps. Upon further examination of the popliteal artery, no trace of ulceration could to our surprise be detected, so that in all probability the very sudden and copious bleeding, which was described to me at the time I tied the femoral artery, must have proceeded from branches only, opened in the same way by ulceration, and bleeding probably thus furiously in consequence of their having been opened, as they were at the present time, very near the main trunk.

Perhaps some gentlemen may ask, as this patient had hospital gangrene, which is a constitutional disorder, why amputation was performed, or why, being performed, the disease did not return in the stump? You will observe, however, that the operation was performed, not because he had quite recovered that state of constitution which we should have wished, but to prevent the more pressing danger of death from bleeding; and also, that although the bleeding took place from phagedenic ulceration, yet the constitutional state on which it depended was very nearly corrected, and the wound was improving, so that the bleeding was rather from the ulceration during the separation of the sloughs, than from any recurrence or spreading of the phagedenic action. Although, therefore, amputation is obviously improper in hospital gangrene, which attacks even the least touch of the lancet, when it prevails, this rule would scarcely apply to our present case.

After the amputation, which he bore with the same perfect quiet which had been remarkable in the former operations, great care was necessary to prevent his sinking from the effects of the quantity of blood he had lost beforehand. He lay during the night, with copious perspiration and a rapid pulse, scarcely perceptible, in a half dreaming state, though not delirious, and incapable of even turning his head on the pillow, from exhaustion. Some gentlemen were kind enough to stay with him during the night, and give him constantly some small quantities of wine and water, sago, beef tea, and other things of this sort, to prevent his sinking. The next day, the 26th March, he had a little sickness, which was stopped by a small quantity of brandy and water, and he enjoyed a beef-steak.

28th.—The stump had in part united, though beginning to suppurate extensively,

and afterwards went on very well; so that by the end of April the wound was gradually closing, and he could sit up on the outside of the bed.

[The immense mass of new bone in the part which had been removed was shewn to the pupils, the cavity in which was of considerable size, and had still some small spiculae of dead bone lying in it. The femur, at the part where it was sawn through, was considerably enlarged by new bone, and the whole of its cancelli obliterated.]

Since the lecture was given, Chandler has left the hospital quite well.

ST. BARTHOLOMEW'S HOSPITAL.

Erysipelas of the Head and Face—Ulceration of the Bladder, and effusion of Urine into the Cavity of the Abdomen.

ANN HALL, aged 40 years, was admitted into Faith Ward, under the care of Mr. Lloyd, on the 2d of July, with erysipelas of the head and face. The inflammation seemed to be on the decline, and partial desquamation of the cuticle was taking place. There was some heat of skin, thirst, and a white fur on the tongue. Pulse 100, without much power; no pain in the head, or disturbance in the sensorial functions; bowels freely open. She has been suffering from illness during the last month, but no distinct account of its nature can be obtained. The erysipelas came on some days previous to her admission.

Caput radat. Hyd. cum Cretâ, gr. iiss., in formâ pilulâ, ter quotidie sumend.

R Mist. Ammon. Acet.; Mist. Camphoræ, aa. f. 3vj. ft. haust. 4tis hor. sumend.

3d.—The erysipelas still declining. Pulse 110, feeble; complains of feeling very low and weak.

Rep. Mistura; cuique dosi, adde Ammon. Carb. gr. iij. Strong broth.

5th.—Bowels much purged.

Adde Tinet. Opii, mv. cuique dosi misturæ.

8th, 6 P.M.—Was suddenly seized with acute pain in the abdomen, attended by complete collapse. Pulse scarcely perceptible; body covered with a clammy perspiration. She died in about twenty minutes from the accession of this attack.

Postmortem Examination, fourteen hours after death.—On laying open the abdomen, about a pint of fluid, having a strong urinous smell, was found in its cavity. There were marks of general peritonitis, and lymph was plentifully deposited on the posterior surface of the uterus and on the peritoneum, covering the parietes of the lower and back part of the abdomen.

The posterior part of the bladder was perforated by an ulcerated aperture, elongated in form, and presenting ragged edges: the coats of the organ did not otherwise exhibit any marks of disease. The mucous membrane of the stomach was throughout in a state of gelatinous ramollissement.

The left side of the chest was found to contain a quantity of turbid serum, and a layer of recent lymph was deposited on the surface of the pleura covering the lung, and on that lining the parietes of the thorax.

Wind N.W. and S.W., the former prevailing.
Except the 5th and 6th, generally cloudy, with frequent rain.
Rain fallen, .175 of an inch.

NOTICE.

We regret that we cannot give insertion to the letter of "Justus." Whatever the merits of the case may be, it is contrary to all usage to publish anonymous and unauthenticated charges against parties who are named. We certainly doubt the expediency of entering upon the disputes at any school, "without the authority, consent, or knowledge," of any of those concerned: nevertheless, if our correspondent chooses to do so, in his own name, we shall insert his letter.

W. WILSON, Printer, 57, Skinner-Street, London.

LECTURES

ON THE

THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

—
DISEASES OF THE URINARY
ORGANS.

—
LITHIASIS.

Symptoms of stone in the bladder.—Supposing that there is a stone in the bladder, the symptoms that are produced are usually a particular pain at the end of the penis—a pain which the patient describes as a benumbing pain, and which is increased upon exertion. This pain makes the patient pinch the penis as hard as he can; and if he feel a sudden call to make water, he usually puts his hand to the end of the penis; and children are in the habit of pulling the prepuce. There is a frequent desire to make water, and the stream suddenly stops, the desire, however, to make water being still urgent. Sometimes a change of posture will cause the urine to flow again. Sometimes the urine, instead of suddenly stopping, will come away drop by drop, the discharge being attended with great pain, and perhaps with blood. There is pain in the bladder itself, especially on motion, and pain likewise on evacuating the intestines—and tenesmus. If the calculus be large, or very rough, there is pain in the neck of the bladder, pain and numbness of the testis of the same side, pain of the inner part of the thigh, along the course of the anterior crural nerve, and sometimes down to the foot, so that there is pain actually in the sole of

the foot; and all these symptoms are rendered worse by exercise.

Now pain at the end of the penis, pain increased too on motion, and increased whenever the desire to make water comes on—a frequent desire to pass urine—a voiding of it drop by drop—tenesmus, and the presence of blood in the urine, may occur when there is no stone whatever. I have had every one of these symptoms two or three times over in my life, from mere inflammation about the neck of the bladder.

The sudden stoppage of the stream is the sign most to be depended upon. Disease of the prostate, and inflammation at the neck of the bladder, will cause many of the other symptoms. Dr. Heberden says that the pain on voiding the urine is felt *after* making water, in the case of stone in the bladder; and worse *before* passing it, in the case of diseased prostate; and that in the latter case it is not increased on motion;—and I believe this is a general fact. The obvious reason why the pain is increased on motion, in the case of a stone in the bladder, is this: the stone is moveable, and therefore it may come forcibly in contact with different parts of the organ by motion, whereas the prostate is fixed. However, the prostate is rarely diseased except in the case of old men. Dr. Heberden says that even pain and swelling of the testes are observed sometimes in disease of the prostate. But you may always ascertain whether the prostate is diseased by passing your finger up the rectum, and observing whether it is enlarged; and the certain way of ascertaining whether there is a stone in the bladder, is, of course, to sound the patient. There is frequently in the latter case a large quantity of ropy mucus secreted, which you may draw out to a considerable length, and which subsides in the pot to the bottom of the urine, in the form of a white tenacious mass.

Occasionally a small fragment of a calculus comes away; and when all the symptoms have become violent, whatever deposition there formerly was in the urine—whatever was the diathesis before—it now becomes phosphatic; the urine becomes pale and copious; it loses its acidity, and has great alkalescency; and if there be any deposition at all, it consists of the phosphates. The agony in this state of things becomes constant, the patient becomes emaciated, and death ensues. The phosphatic diathesis and the sufferings are proportionate.

Morbid appearances resulting from calculi.—The bladder after death is found to be diseased; the mucous membrane becomes diseased, the muscular fibres enlarged, and perhaps the kidneys themselves diseased.

Removal of the stone—Cessation of the symptoms.—This state of things may be prevented generally by the removal of the stone by surgical operation; and sometimes it fortunately ceases through a sac being formed in the bladder. The muscular fibres give way, and the inner coat protrudes between them: not that the muscular fibres rupture, but the inner coat gets between the bundle of fibres, and you see externally a small protuberance on one part of the bladder, consisting simply of mucous membrane internally, and peritoneum externally. Sometimes, if the calculus be rough, the symptoms diminish by the deposition of the phosphates. Although the phosphates are in general produced by irritation, yet they fill up the interstices between the roughness of the calculus, and so render it smoother than it was before; and in this way the symptoms are sometimes alleviated.

Calculi not necessarily productive of symptoms.—But it is to be remembered, that although a stone may produce all these symptoms, yet it does not necessarily give rise to them. If the calculus consist of lithic acid, it may be small and quite smooth, and then it may give very little trouble; indeed, such a calculus has been found after death, when its presence was not at all suspected. The health is sometimes very good in such cases; and if the health be fair, and the patient does nothing calculated to injure him, a calculus of that kind may not increase. When a person by sounding is known to have a calculus in the bladder, yet it may go on for many years without any increase, provided he does nothing unfavourable—that is to say, does not commit any excess, does not increase the feverishness, and adopts a moderate antiphlogistic plan. Dr. Prout knew a case in which the presence of a stone in the bladder was ascertained by sounding; and five or six years afterwards, at the time he mentioned it to me, the patient

experienced little or no trouble from it; and frequently for weeks together the patient forgot that he had a stone in the bladder, or any thing the matter with him. But the case had been well managed; and the patient had been put on a moderate antiphlogistic regimen, such as I before mentioned. Dr. Prout also mentioned to me, that he knew a case where four renal calculi existed in the bladder five months without producing any severe symptoms; and then a little irritation occurred at the neck of the bladder, which led to their removal; and yet one of them was nearly an inch in length. These, however, were lithic acid calculi.

Oxalate of Lime and Phosphatic Calculi always cause suffering, and therefore should be removed.—The oxalate of lime calculus causes extreme suffering, if it be of any size, and so also does the phosphatic, and an operation is indispensable, (no regimen here will answer the purpose) provided things have not gone so far that a surgeon would not listen to the operation.

Of course the nature of the operation must be determined by the surgeon—whether it is the removal of the stone by cutting, or its reduction within the bladder, or dilatation, or whatever else.

Spontaneous discharge and removal of Calculi by dilatation.—You know that in the case of the male, calculi of really considerable size are sometimes discharged, and instruments have been formed to dilate the urethra, so as to bring them away without any incision; but these have been lithic acid calculi. But nature very frequently discharges them herself. However, these occurrences take place far more frequently in the female, of course, than in the male, and much larger calculi have been brought away both by nature and by artificial dilatation. One has been discharged weighing as much as 12 ounces in a female. These are very extreme cases. It is very common for females to pass calculi by an effort of nature, on account of the shortness of the urethra; and it does not appear that females are by any means so subject to the complaint as males.

Great suffering induces a deposition of the Phosphates.—When the suffering has been very great, and an operation has at last been performed, it is generally found that the calculus externally is of a phosphatic kind; but an entire phosphatic calculus is rarely seen. In this state of things, when the phosphatic diathesis exists, the kidney is at first affected only functionally: it secretes morbid urine, through an irritation of the urinary organs, with an excess of urea, with a tendency to a phosphatic deposition, but at last actual structural disease of the kidney takes place. If the kidney could be preserved in a state of

functional health—if it could be made to secrete proper urine, although a stone exists in the bladder, yet it is probable that it would not increase even around an accidental nucleus; but the accidental nucleus produces irritation; that irritation is communicated to the kidney—the kidney secretes morbid urine—from the morbid urine deposition takes place, and so the calculus increases. The moment the urine becomes unhealthy, then a deposit takes place, and the mischief goes on increasing. Frequently, in the origin, the disease does not depend upon any external circumstance, but there is a real disposition to these morbid deposits which gives rise to it, and it goes on increasing till a calculus is formed; but if by chance any thing gets into the bladder—a piece of bougie or a drop of blood, so as to form a nucleus, this, by inducing irritation, will cause an increase of it. If by art we could keep the urine healthy, it is supposed that a calculus would not be formed—that the nucleus would not serve for any thing to collect around.

Calculi do not regularly increase.—It does not appear that a calculus goes on regularly increasing; the urine is not always equally morbid, the irritation is not always equally felt, and external circumstances are not always equally unfavourable. The patient neglects himself from time to time, or some unfortunate occurrence takes place; in short, the urine is not always in the same morbid condition, and therefore the calculus does not go on increasing regularly at the same rate. Sometimes a calculus has been known to increase very much, and the state of the urine to become more and more morbid, and then the process has been exceedingly slow again. And there is another reason to make us suppose that the deposition is not constant: many calculi have a laminated structure, and between the laminae they appear to have suffered some diminution: there is a space, and they frequently look as if they were worn by water moving around them. The occurrence, indeed, of separate laminae is considered to prove that particular circumstance.

Calculi should be removed when the patient is under puberty.—It is not only where there is great suffering, or where the urine has become phosphatic, however, that an operation is proper, provided the case is not too far gone; but if the patient be below puberty, even although the sediment is not phosphatic, but is red, and consists of lithic acid and lithate of ammonia, then it is considered that the calculus should be removed. If the individual be below puberty, there are five thousand chances to one of the calculus increasing, and giving further trouble, and though the patient may not

be suffering much, it is generally best to extract it.

Mortality from Lithotomy.—Lithotomy is considered to be less dangerous in children than in adults; it was found at Norwich to be four times less. Generally speaking, the ratio of mortality from lithotomy is about one in seven and three-quarters; but in Norwich it is said to be less than any where else, so that in forty years Dr. Marcet found that the average of mortality there was but one in eleven and three-eighths; before puberty one in eighteen, and after that period one in four and three-quarters.

Ages at which Calculi most frequently occur—*Females less subject to the affection than Males.*—Nearly one-half of the cases of stone in the bladder are found to occur before puberty, and then there is an increased number again after forty; and but one female was affected with stone in the bladder for twenty-three males. Some ascribe this to the quiet habits of the female—to the circumstance of their not being subject to laborious exercise; and others ascribe it to the shortness of the urethra. The latter circumstance must have great influence, but in all probability there is less disposition in them to the disease.

These are the only considerations for the medical practitioner; in regard to the performance of the operation, of course I have nothing to do with it. All that we have to give an opinion upon is the condition of the urine; the suffering, on the one hand, and on the other the age of the patient.

CYSTITIS.

The urinary bladder is of course subject to inflammation, and this is called *cystitis*.

Symptoms.—The symptoms are, a burning and throbbing pain in the hypogastrium; tenderness on pressure; a very frequent desire to make water; a most horrid pain at the neck of the bladder while the urine is passing, so that perhaps the patient can only void it on his knees. The urine is made in a very small quantity, perhaps every ten minutes; and it is often high coloured, perhaps bloody; and there is also tenesmus.

Causes.—This affection is induced by boils, by turpentine, cantharides, and things which peculiarly irritate the urinary organs; but more particularly by gonorrhoea: the inflammation of the urethra spreads inwards, and then you have inflammation of the bladder.

Treatment.—The treatment is of course simple enough, but it requires to be put into practice vigorously.

CYSTORRHOEA.

The bladder, however, is subject to chro-

nic inflammation, and it is still more subject to an affection of the mucous surface, in which there is a great discharge of ropy mucus, such as occurs when a calculus exists in this part, and causes great suffering. There is not only this quantity of ropy mucus secreted, but the mucous membrane itself becomes hypertrophied. As much as several pints of this ropy mucus have been known to be discharged in a day, but it is very common indeed for a pint to be discharged. It subsides to the bottom of the vessel, and is quite white. It sometimes blocks up the urethra, so that a little difficulty is experienced from time to time in making water, and at last it is really purulent.

Morbid Appearances.—After death, if it prove fatal, there is frequently a thickening of the mucous membrane to a great amount; the muscular fibres are seen distinctly, and in some parts of the bladder are very much developed; indeed it would seem that those muscular fibres described by Sir Charles Bell, which run from the extremities of the ureters, become hypertrophied, and the mucous membrane suffers, so that at the opening of the bladder you see a triangle running from the mouth of one ureter to the other. You sometimes may pass your finger down half an inch, so great is the development.

Treatment.—The treatment of this sort of case must be antiphlogistic, so far as the patient's strength will allow of it. The frequent application of leeches is proper; and if there be no excessive irritation, but more discharge than any thing else, turpentine has been occasionally used in a small quantity, and uva ursi. You may put an ounce of the latter to a pint and a half of water, and boil it down to a pint. Cubebs likewise have been occasionally serviceable. These cases, however, taken altogether, are very bad; and in a large number of instances a stone exists in the bladder, or there is a stricture, which gives rise to this irritation, to hypertrophy, or diseased prostate. If the urine be alkaliescent (deficient of acidity), it may be well to give acids and narcotics, in order to lessen the irritation; and for this purpose you may give conium, opium, and hyoscyamus. But when the mucous membrane becomes hypertrophied, and there is secretion to such an amount as this, you can do little more than afford temporary relief.

So great is the disposition to hypertrophy of the muscles of this part, that it is said that no other muscles of the body are so increased by exercise as the muscular portion of the bladder—that is to say, if any difficulty exist in the passage of the urine, or there be any irritation about this part, so as to make the bladder contract

frequently, no other muscles grow to the same amount. Indeed, in some cases, the inner part of the bladder looks like the inner part of the heart; the muscular fibres and the mucous membrane are so developed that at first sight you would think it was the right ventricle of the heart.

GENERAL MORBID ANATOMY OF THE BLADDER.

Hypertrophy.—In regard to the morbid anatomy of this organ in general, the mucous membrane is often softened when it is hypertrophied and when it is not. Sometimes the villi and the follicles are so apparent that you perceive them instantly; naturally they are so minute that you cannot see them. The cellular membrane is frequently hypertrophied, so that the bladder will become hard, and if a sound be passed into it the hardness is discovered. The mucous membrane is sometimes enlarged, so that you have the appearance of a polypus.

Fungous Excrescences.—Sometimes fungous excrescences take place, of a cancerous or encephaloid nature. I mentioned a case of this kind formerly, where encephaloid deposit gave rise to hæmorrhage which destroyed the patient.

Scirrhus Tumors.—Scirrhus tumors are found in the bladder, which are sometimes original, and sometimes connected with disease of other parts—with a diseased rectum, or a diseased uterus.

Cysts.—A cyst has sometimes been found in the organ, and it is almost always connected with its internal surface; and in this case it is most probably a mere sacculus. A sacculus, however, may be formed originally. The bladder has sometimes been divided into two chambers by adhesions across; or a sacculus may become so very large as to be of the same size as the bladder itself.

PARALYSIS OF THE BLADDER.

The bladder is continually the subject of palsy. When a person labours under paraplegia (a loss of power of the lower extremities), he is generally unable to retain his urine. At first he is unable to make water, so that it continually requires to be drawn off, (this you see in paraplegia from accidents) and then, after a time, the detrusor urinæ muscle loses its power altogether, and then the sphincter also loses its power, so that the patient cannot retain his urine.

But these parts are much disposed to become diseased in old men, just as the uterus and the ovaria are disposed to fall into disease in old women. When the prostate and the parts of generation have done their duty, they fall into

a diseased condition, just as similar parts do in women, and the bladder among the rest; so that old men are continually unable to sit like young ones, and they will be obliged to go out of the room from time to time.

But sometimes this will occur from accidental circumstances. I have known paralysis of the bladder occur (and this is worth knowing) from an opiate injection;—from having a suppository, or an injection of opium, the bladder has become paralysed, so that it has been necessary to draw the water off, and it has occasioned much alarm. On a repetition of the injection, the bladder has become so torpid that retention of urine has actually occurred. Sometimes it is produced by a torpid state of the system, where the head is oppressed: it is a thing which occurs frequently in fever; and sometimes, without any obvious reason, the bladder loses its power, just as any other part of the body may do.

Treatment.—If there be no disease of the spine, no organic disease of the organ, no inflammation, nothing more than the simple fact itself, without your being able to trace it to any thing more than torpidity, then cantharides is one of the best remedies, and perhaps electricity; any thing that is stimulating.

Stillicidium Urinae.—You of course are aware, from other lectures, that the bladder may be in this state while the urine is dribbling away; for when it is distended to a certain amount, the urine will pass *guttatim*, involuntarily. The patient will tell you that he cannot hold his water, while in fact the bladder is full, and can hold no more. It is therefore necessary, in these cases, to ascertain the condition of the bladder. Very frequently it happens that this form of paralysis takes place temporarily. If a person do not make water in proper time, he loses the power of voiding his urine, and distention is no longer felt: the muscles have no longer power to empty the bladder, and it remains greatly distended, although the urine is constantly coming away; and therefore when you are told that a person cannot hold his water, you have to ascertain whether he is not holding too much, and cannot hold any more.

DISEASE OF THE PROSTATE.

Enlargement.—In regard to disease of the prostate itself, you will continually be consulted upon it, as it occurs so frequently in old men. From the pressure, there is frequently a great difficulty in making water, and sometimes it acquires so very large a size that there is difficulty even in going to stool. There is pain there, and the abdomen at last falls into a state

of disease, and death is frequently the consequence. You will, after death, find the prostate full of large cells; it is very much hardened, and perhaps it has acquired an immense size. This may be ascertained during life, by the introduction of the finger into the rectum.

Calculi.—Calculi frequently come from the prostate, and they are sometimes found in a very large quantity in the cells of the prostate. Occasionally they will grate against a sound when it is passed on towards the bladder. They are generally small—sometimes exceedingly small; and always, I believe, found to consist of phosphate of lime.

Treatment.—In regard to the treatment of disease of the prostate, the chief you have to do is by means of surgery—drawing the water regularly off. However, it is sometimes necessary, on account of the great pain, to employ narcotics; and I think it would be worth while, in such cases, to give iodine a fair trial—to rub iodine and hydriodate of potassa externally, and give it internally. I have not had many opportunities of treating such cases, because they generally fall to the surgeon; but occasionally I have treated them, and temporary benefit has ensued. I have had two or three patients in whom there appeared to be a temporary alleviation of the complaint; and if any thing would afford temporary relief it would be iodine. I do not know whether it would cure a case of this description, but I should expect to do more good by it than by any other remedy.

GOUT.

I have now finished the consideration of diseases of the urinary organs, so far as it is incumbent on me to speak of them, and I will now speak of an affection which is very much connected with disease of the urine, although it is another complaint: I mean *gout*. When persons have the gout, I am never surprised if they have stone—gout and stone so frequently go together; though gout is a disease which affects the joints in the first instance.

Etymology.—It is called the gout from the Latin word *gutta*, or the French word *goutte*, which comes from the Latin word *gutta*—a drop; because it was supposed to arise from a deposition of drops from some morbid fluid in the joints. In Latin, it is now generally called *arthritis*—inflammation of the joints. In the classics it is spoken of under the head *podagra* when it affects the feet, *chiragra* when it affects the hands, and *gonagra* when it affects the knees; but all these *agra* are comprehended in the term *arthritis*. Although this term means inflammation of a joint from any cause, yet it is now appropriated solely to gout.

Invasion.—When this affection makes its first attack, it generally begins at two or three o'clock in the morning; just at the time that a fit of asthma commences, and indeed some other diseases. Usually it first attacks the ball of the great-toe. The patient wakes in most excruciating pain with the disorder; he then becomes feverish, and continues in this state till the next midnight, when the pain remits, and the following morning he finds his toe swollen and reddish; and he has exacerbations of this for several days and nights. The disease then frequently declines, the patient perspires freely, and the part itself loses its cuticle; the cuticle desquamates (which is not the case in most diseases), and there is violent itching for some days; and then there is an end of the business.

Progress.—After a time, sooner or later, the same thing occurs again; perhaps attacks the balls of both great-toes, perhaps flies from one to the other, and affects the hands, the knees, or the wrists; and so it will shift its place during the same attack, running from one knee to the other, from one wrist to the other, from one ankle to the other, from the hand to the feet, and *vice versa*. The more frequently it comes, the less probability is there of its being confined to the fingers or toes; it is more likely to spread from the ankle, from the wrist, or even from the elbow and other joints; perhaps the shoulder becomes affected. But it begins at first in the smaller joints, and affects them to the last, going to the others only occasionally.

Generally the intervals of the attacks grow shorter, the patient has more and more frequent fits, and they frequently last longer.

The joints at last may become stiff, rigid, and deposits will take place under the skin; so that the joints of the fingers and toes become enlarged, swollen, and are harder than natural. Occasionally a solid deposition takes place of white stuff, and sometimes it is fluid; so that if you prick the part which is soft with a needle, you squeeze out a quantity of stuff like soft mortar. Not unfrequently there is a nephritic attack; an attack of inflammation of the kidneys, and a deposition of lithic acid, or some compound of it. Occasionally these things take place with the gout; occasionally they take place only during the intervals; but a deposition in the urine and a fit of the gout, where there is deposit in the joints, are frequently very closely connected.

General health improved by the Gout.—After the attack, people are generally better than they were before; they find it does them good, and therefore they are not at all sorry that they have had the disease.

Many persons long for a fit of the gout; they say that gout is in the family, and if they had an attack they should do well, when they have not had it before; and those who have had it, if any thing be the matter with them, they are satisfied that they should be a great deal better if they had another attack, and many people try to bring it on.

Premonitory Symptoms.—Before the attack, there is frequently indisposition of some sort—the symptoms that I mentioned under disorder of the digestive organs; or languor, or lowness of spirits, or perhaps pain of the head, or wandering pains, gouty pains coming and going in the larger or smaller joints, sometimes palpitation and giddiness, functional diseases in almost every part of the body.

Atonic Gout.—If these symptoms exist for some time, so that the patient really feels himself diseased, it is called atonic gout—gout without strength, gout where there is not sufficient strength to bring it out;—a gouty disposition exists, but there is not activity enough to bring it forward.

Retrocedent and misplaced Gout.—Sometimes when the gout has come on in a very satisfactory manner, it will suddenly cease—not retire to another joint, but will suddenly cease, and the patient shall have some severe internal affection—perhaps apoplexy, perhaps violent vomiting, gastrodynia, or perhaps violent colic—something severe within, and it is then called retrocedent gout. Sometimes the affection within is of an inflammatory nature, and then it is called *misplaced gout*; but it is no matter whether we call it retrocedent or misplaced, for very often inflammation, in former writers, is ascribed to some nervous affection, or something else. You have only to consider, that if the gout does not come out satisfactorily, it is atonic gout; whereas, if it suddenly ceases, and an internal part is affected in a violent degree, it is retrocedent or misplaced gout, according to the affection that is going on.

Symptoms relieved by Gout.—Some persons have had very extraordinary symptoms relieved by gout. I knew a gentleman who had had pain of the stomach—gastrodynia, for many years; I know not how many, for he did not attend to it much; but at last a fit of the gout came on, and he has never experienced the pain since. Palpitation, which has existed for a long time, has frequently ceased upon the occurrence of a fit of the gout. Strangury, cystorrhœa, piles, and almost every disease you can mention, has ceased on the appearance of gout; and sometimes they alternate with gout; and if such affections be very violent indeed, then they may be called misplaced gout; for they have come when it should have appeared.

Predisposing Causes.—The disease at first most frequently commences about the end of January or the beginning of February: there is no universal rule, but it occurs more frequently than at any other time. It occurs in males much more frequently than in females, just as is the case with regard to stone. It occurs, too, it is said, in robust males far more frequently than in weak ones. It never has been known in eunuchs; at least so it is said. If such were the case, gouty old gentlemen have an easy remedy. It is also a disease that is very hereditary: this is one of the great hereditary affections. If it occur in females, it is generally—I do not say universally, because I have seen the reverse myself—in masculine females; those who have a little touch of the male in them; robust, hearty-looking women. It occurs in men particularly who have circular chests, short necks, and broad heads, such as are called *thick heads*—not those who have large foreheads, but bulky heads altogether, and who are of full habit. It occurs chiefly in those who eat a great quantity of flesh meat, and drink a good quantity of wine. Among those who are predisposed to it, it seldom occurs till after thirty-five years of age. I have seen it in persons below puberty, and it is said to have occurred in infants; but more frequently than not it takes place in those who are above thirty-five, who indulge at the table, and are of plethoric habit. Such are the predisposing causes.

CLINICAL OBSERVATIONS

ON THE

LIGATURE OF THE PRINCIPAL ARTERIES.

By BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

TYING the trunks of the great arteries may be regarded as among the most brilliant achievements of modern surgery. Formerly, those unfortunate individuals who were affected with aneurism of those parts were doomed almost to certain death, for spontaneous cure was a very rare occurrence. Sometimes, indeed, the aneurism terminated in inflammation, leading to the suppuration or gangrene of the cyst, or the disease ceased by the tumor producing such pressure as led to the formation of a coagulum. But these facts were lost to science.

One of the great difficulties which long operated in arresting the surgeon related

to the re-establishment of the circulation: how, in fact, was it to be conceived that life could be retained in the limb after the ligature of the brachial or femoral artery? The collateral arteries did not seem sufficient to supply their place. These fears were in part dissipated after Anel made known his method, and speedily yet more venturous attempts were made, ligatures being applied to most of the great arteries. In some, however, the proceeding of Anel was found not to answer, as in those where the aneurism is situated in the primary iliac, or at the origin of the carotid. Hence arose two great divisions in these operations; namely, 1, the application of ligatures between the aneurism and the heart; and 2, the application of ligatures between the aneurism and the capillaries; the former of which I shall now proceed to consider.

Ligature between the Aneurism and Heart.

I shall say nothing of the depleting system of Valsalva, except that when carried to its fullest extent, it lessened the action of the centre of circulation less than it diminished the resisting power of the aneurismal parietes; while, on the other hand, when the practitioner, at length wearied with the attempt at cure in this manner, again begins to recruit his patient for the operation, the tumor under the change assumes a more rapid development, and such as may prove fatal, especially if the aneurism be situated about the subclavian or iliac regions.

Ice, snow, and similar applications, are sometimes employed with advantage in these aneurismal tumors, which cannot be said of plaisters, astringent powders, or any such means, which indeed have now been generally abandoned. Pressure above the aneurism has, however, been frequently employed of late, and with advantage. Of the different kinds of instruments used for this purpose, the compressor is almost exclusively preferred. It is composed of a semicircle of solid steel, two inches in breadth, from three to four millimetres in thickness. At one of its extremities, and on its concave surface, is fixed the pad, which is to constitute the *point d'appui* on the limb just opposite the artery. At the other extremity of the semicircle is a second piece of iron which supports another rounded pad slightly elongated, and capable, by means of a screw, of being approximated or separated from the other which is opposed to it. The curvature of the instrument may be increased or diminished by a very simple contrivance, and the instrument is constructed of different sizes, for the arm or thigh, and for infants or adults. One of the larger size, and one of the smaller suffice, for all ordinary purposes.

The action of the instrument may be readily understood. It stands on the limb detached and free, only touching the two opposite points, thus arresting the circulation only in the principal trunk, while that of the collateral branches is left free. Nevertheless, some persons cannot bear the instrument, and we then are driven to the ligature, which is, after all, the most efficacious of the various methods that have been proposed.

The proceeding generally employed at the present day is that of Anel or Hunter. When an artery is tied in this manner, it must be laid bare at some distance from the aneurism, that it may be perfectly sound, and it ought also to be as near the surface as may be. A precept of not less importance is to retain above the incision a sufficient number of collateral branches to keep up the circulation in the lower part of the limb after the operation; while, further, the ligature must not be too close to large branches, particularly above, as their too close proximity is one of the most frequent causes of consecutive hæmorrhage. The external incision must be sufficiently large to admit of free manipulation with respect to the vessel, and the aponeuroses must be more extensively divided than the skin.

The diagnosis is easy while aneurism is recent, but difficult when it is old, large, and irregular. But if an artery is, as it were, surrounded by a cyst, a chronic abscess, an engorgement of the cellular texture, by blood, by a gelatinous effusion, then we must be on our guard, for there is no situation in which such affections may not be confounded with aneurisms. Another condition proper to be aware of is this:—the aneurism may burst at one small point—the blood may become infiltrated by degrees, and travelling along the cellular membrane form bloody tumors, which do not pulsate, nor present any of the other characters of aneurism. I remember a curious case of this kind: the blood, after escaping from an aperture in the aorta, found its way to the neck, and there formed various tumors, the opening of which was followed by hæmorrhage, which was not considerable, but being constantly repeated led to the death of the patient.

In the month of April 1810, a woman, aged 66, and whose integuments were of remarkable flexibility, came to the Hotel Dieu for a gangrenous eschar on the right elbow, at its inner part, and which was accompanied by an oedematous infiltration of the arm, with absence of the pulse. On being questioned, she stated that two months previously she had experienced a fall, followed by acute pain, especially about the shoulder; but that a surgeon who attended her was unable to discover

either fracture or dislocation. The pain continuing, she consulted another person, by whom violent extension by instruments was employed, after which the swelling of the limb took place, and the eschar formed at the point where pressure had been made by the apparatus.

The eschar became detached after a short time, and nothing particular occurred till the twenty-first day after her admission, when she complained of a tumor in the axilla of the same side, which had begun to be developed some time before; she could not tell how long. This tumor was already large: it raised the clavicle and the pectoralis major, preventing the arm from being brought close to the body. It was moderately painful; without change in the colour of the skin; did not pulsate, and communicated a sense of deep-seated fluctuation. I was then second surgeon, and the surgeon in chief was absent. I thought that it might be a chronic abscess; however, its situation made me uneasy, and I resolved to wait. During a few days' attentive examination of the tumor, it was perceived to increase, and the pain also augmented, while the fluctuation became more distinct. I then resolved to open it; but still, having some doubt about it, I determined only to make a puncture of exploration. With this view I took a very narrow bistoury, with an acuminate point, and plunged it into the most projecting part of the swelling. In place of pus, arterial blood flowed. Adhesive plaster and a bandage were applied, and on the arrival soon after of the surgeon in chief, it was determined to tie the subclavian artery. He applied his hand beneath the upper and anterior part of the apparel, and felt distinctly the pulsations of an aneurismal tumor. The bandage was removed, and then no one could perceive any pulsation. It was now again doubted whether it were really an aneurism, or whether a small artery had not been opened in the parietes of an abscess. However, continued observation led to the detection of obscure pulsation, with dilatation, at the point where the clavicle was raised. It was soon further made out that there existed two tumors; one of small size beneath the clavicle, presenting pulsation; the other very considerable, fluctuating, and at the upper part of which was with difficulty detected an obscure sound, analogous to that which accompanies the passage of blood up an aneurismal tumor. I proposed that a ligature should be applied to the subclavian artery, between the scaleni muscles, and executed the operation on the dead body in the presence of the surgeon in chief and the pupils. He declined to give his consent, and thus was lost to French surgery the honour of first execut-

ing this operation. The method of Val-salva was adopted, and the patient soon died from hæmorrhage, the tumor having sloughed.

The post-mortem examination proved that there were in fact two tumors—one formed by the subclavian artery, dilated through two inches of its course; the other, constituting the principal, communicated with the former by means of a laceration in the artery.

No opportunity presented itself to me of practising this operation till 1819, when a patient was admitted at the Hôtel Dieu with an aneurism in the axilla.

Ligature of the Subclavian performed with success, for a false consecutive aneurism of the left axillary artery.

Charles Chevalier, ætat. 37, a joiner, came to the Hôtel Dieu Feb. 27, 1819, labouring under this disease. Having been made prisoner in Spain in 1811, he attempted to escape, but in his flight was overtaken, and knocked down by a thrust with a sword on the back part of the left shoulder. A large quantity of blood flowed, and he fainted; the hæmorrhage ceased, and the wound healed in three weeks. Two months after the accident, Chevalier perceived in the axilla a little tumor, about the size of a nut, and pulsating. In the course of two years the tumor had acquired the size of a hen's egg, and the pulsations had become stronger. He was afterwards exposed to great fatigue, and the tumor soon acquired the size of a child's head; and finding himself unable to gain his livelihood, he came to the hospital as above mentioned. The tumor was now hard, elastic, and pulsated strongly, synchronously with the heart. The heat and sensibility of the limb were much the same as in health; but the pulse could not be felt in the radial or brachial arteries, while in the subclavian the beating was violent. It was resolved to tie this artery.

The subclavian artery presents three distinct points in its course: first, that before its entrance into the scaleni muscles; second, that portion which runs between these; third, that portion extending from its exit from among the scaleni to the first rib. This last part of the subclavian artery, situated very near the skin in thin persons with long necks, is, on the contrary, very deep in those who have short necks and brawny shoulders, and still more so in those who have the parts pushed up by a tumor in the axilla, as in this patient. Another difficulty, which, however, is common to all, is that at the point in question the artery is so surrounded with nerves, as to render its separation often a matter of difficulty. The second point offers this advantage, that the artery alone

penetrating the interval of the scaleni muscles, is completely separated from the vein which passes before the anterior scalenus, and the nerves which are placed behind. The artery may thus be securely reached in taking the anterior scalenus muscle for a guide. The first point indicated is so deeply hid in the summit of the cone formed by the chest—it is so near the pleura and lungs—that the attempt to apply a ligature ought if possible to be avoided. It was resolved to tie the vessel as it passed through the scaleni; and the patient was bled as a preparatory step. A triple silk thread was applied, and the pulsation in the tumor entirely ceased. Being convinced of the inutility, and even danger, of "*ligatures d'attente*," none were employed; the wound was simply dressed, and bags of warm sand applied round the arm.

Every thing went on well during the first ten days, and on the eleventh the ligature came away, without being followed by any bleeding. By the thirteenth day the wound was nearly cicatrized, and the patient began to use his arm. The tumor was sensibly diminishing, but became so soft as to excite apprehensions of its suppurating. It was covered with pledgets soaked in goulard water, renewed every two hours. By the twenty-eighth day the tumor was reduced to one-fifth of its original size, and the softness and fluctuation had disappeared. The heat and sensibility of the limb were the same as on the other side. The circulation, as in all limbs the principal artery of which has been tied, had a peculiar character, namely, that the arteries shew not the least pulsation, while by the touch it is perceived that they are full, and traversed by the blood.

Chevalier, after a few months, resumed his occupation of a joiner, and enjoyed good health for three years; but at the end of this time, after violent exertion, he was attacked with inflammation and swelling in the axilla, for which he again entered the Hôtel Dieu July 14, 1822. The tumor was as large as the fist, the skin covering it red, the apex purple, pointed, and threatening to burst; there was no pulsation; the patient had rigors and loss of appetite. Satisfied that this tumor was no longer connected with the circulation, I wished to open it, but the patient preferred leaving it to nature. It was poulticed. At the end of a fortnight it opened spontaneously, and discharged a large quantity of pus, and of matter having the colour and consistence of raisins. This had evidently been formed of old blood, altered by the suppurative process going on around it. The opening was enlarged, and the cyst washed out with injections. The patient's health improved, the abscess

healed, and he left the hospital perfectly cured October the 21st, 1822, no tumor or swelling remaining in the axilla.

This case is remarkable in several respects: the size of the tumor, the point at which the ligature was applied, the division of the anterior scalenus muscle, the ease and safety of the operation, and the means employed by nature to get rid of the tumor, are all circumstances deserving your attention.

When an aneurism arises on the axillary artery, not far from the origin of the brachial—when the disease yet recent has made but little progress, the artery may be tied between the tumor and the clavicle; but when the disease is of long standing, when the tumor is large, or when it arises from the axillary artery near its commencement, the ligature must be applied to the subclavian. M. Pelletan attempted to tie the axillary artery immediately below the clavicle, for a large aneurism, a considerable space in this instance still existing between the tumor and the clavicle. After reaching the artery, several trials were made to get the needle under it, but without success, and the operation was abandoned. The patient died twenty-one days afterwards. It is right to state, however, that ligature of the subclavian itself is sometimes rendered impossible, by the development of the tumor and the displacement of the clavicle. The celebrated Astley Cooper, in treating such a case, was obliged to abandon the operation.

What distinguishes this particular operation from others on the subclavian artery is the point at which the ligature is applied, namely, where it is placed between the scalenus, the anterior scalenus being divided. By this proceeding we are equally certain of reaching the artery, by following the external border of the anterior scalenus, and of avoiding either the lesion of the vein or nerves.

The case of Chevalier confirms what the beautiful dissections of Scarpa had shewn, namely, that the parts of the arterial system nearest the trunk have not less numerous communications than those which are more distant. We find in the notes with which Breschet has enriched the work of Hodgson, a case in which the left subclavian and several of its branches had become obliterated by the pressure of an aneurism of the aorta, the parts continuing apparently well supplied.

Case of Ligature of the External Iliac Artery.

Ligature of the external iliac appears at first sight more difficult and dangerous than that of the subclavian; such, however, is not the case. Several proceedings may be adopted. The first consists in dividing

the parietes of the abdomen parallel to the direction of the artery, beginning at the point where it passes under the crural arch, and ascending towards the umbilicus, parallel to the external edge of the rectus muscle. In the second proceeding the parietes are divided in the direction of the iliac artery, parallel to the crural arch, and at half an inch above it; this is the method of Abernethy. The third, called that of Astley Cooper, consists in making, through the parietes of the abdomen, above the crural arch, an incision across, which commences above the anterior and superior spine of the crest of the os ilium, and terminates above the inguinal ring.

The incision, according to the first method, gives an opening parallel to the artery, but which is limited in breadth to the extent to which the edges of the wound admit of being separated; and it is also attended by the risk of involving the peritoneum. The incision parallel to the crural arch, being at right angles to the artery, affords great facility in the various steps of the operation; and, besides, it is made just where the peritoneum abandons the abdominal parietes to be reflected on the pelvis, and where cellular tissue and fat fill up the triangular space left at the point of separation. This gives more facility in turning aside the peritoneum; it may, however, produce the risk of wounding the epigastric artery, if the incision be carried beyond the inguinal ring. The ligature in either case may be applied at a greater or less height. When very high, we get far from the tumor, but incur the hazard of opening the peritoneum; when very low we avoid this danger, but the ligature comes so close to the tumor, and the origin of the epigastric artery, that the aneurism may become secondarily affected with inflammation; and its inferior extremity continuing to be traversed by the blood of the epigastric, may preserve its calibre, and keep up the circulation in the aneurismal tumor. The following case will serve to illustrate the application of these principles.

Francis Berger, an old soldier, aged 45, of strong constitution, sanguine temperament, irascible disposition, made an effort in June 1815 to raise a plank, one end of which rested against the left groin. He experienced sharp but momentary pain in the part, but which did not prevent him from continuing his work. At the end of two months he perceived, about two inches below the crural arch, a tumor the size of a hazel-nut, which was perfectly indolent, and to which he paid no attention. This tumor made almost insensible progress till June 1816, when the patient having again made a powerful exertion, the tumor suddenly acquired the size of a hen's egg, and soon after was still further increased, so that

he was fain to seek advice, and entered the Hôtel Dieu August 23, 1816.

The tumor occupied the course of the left femoral artery, and had then the size and shape of a large pear, with the base upwards. If compression was made at the end of the abdominal aorta, on that part of the external iliac which corresponds to the horizontal portion of the pubes, all movement in the tumor was suspended, while at the same time it diminished in size and tension.

Two methods of treatment might have been adopted—compression and ligature. If the former did not answer, it would at least facilitate the success of the other. I had a machine constructed by Sirhenry, one of our most intelligent cutlers, by means of which the sacrum being taken as a *point d'appui*, compression was made with a pad and screw on the extremity of the external iliac. This instrument being applied about half an inch above the crural arch, the circulation was perfectly suspended in the arteries beneath as well as in the tumor, to which a bladder of pounded ice was applied.

Such was the first apparatus employed in the case of Berger, and we did not fail speedily to perceive its imperfections. Pulsation returned in the tumor whenever the patient spoke, coughed, or made the slightest movement, and the pain became intolerable, especially during the application of the ice. Various improvements were made upon the instrument, but none of them proved efficacious, and it was abandoned on the 18th of September, at which time some apparent diminution in the tumor had taken place. Another instrument was then had recourse to, and persevered in till the 9th of October; when Berger positively refused to submit to it any longer, notwithstanding that hopes were entertained of its proving successful. The patient earnestly demanding to be operated upon, it was resolved to comply with his wishes on the 16th.

[An elaborate account was then given by M. Dupuytren of the various stages of the operation. To the English student it is enough to say that the method of Sir Astley Cooper was adopted: but a ligature, *d'attente*, was applied, and brought out at the upper angle of the wound; the ligature which was tightened being at the lower angle.]

During the day the patient experienced no numbness of the limb, and the heat remained the same as in the other members. The countenance, however, was changed, and he had a good deal of pain in the abdomen, with constant eructation, followed by fever and great anxiety. He was bled, had infusion of camomile and

anise, with dry friction, to the abdomen. Next day, the heat of the limb was greater than that of the opposite side; the pain at the epigastrium was very acute, and the stomach very much distended. The pulse less developed than the preceding evening; the face pinched; the tongue dry and black. A lavement was ordered, consisting of a decoction of tamarinds—two ounces of the fruit to eight of water; but as this did not produce any effect, a second was given, composed of two ounces of tamarinds to ten of an infusion of camomile flowers. This was returned in a short time, tinged with fecal matter, and it produced the discharge of much flatus, which relieved the patient for the moment and procured him a little sleep. But the pain in the epigastrium soon recurred, and it was attended with a constant evacuation of gas by the mouth. In the middle of the day the face became strongly coloured, the pulse hard and frequent; the pain extended to the hypochondria. Two palettes and a half of blood were taken from the arm; emollient lavements and lemonade were prescribed. The pains were thus soothed a little, and some hours' sleep obtained.

In the evening the mind was somewhat disturbed; the patient did not recollect any thing that happened during the day; the epigastrium was constantly painful, tense, and resonant on percussion. Eructation continual; the tongue red and dry; the pulse hard and frequent. Bleeding again to two palettes in the night. By means of lavements, and particularly by the repeated introduction of a gum elastic sound into the rectum, a great quantity of flatus, but no fecal matter, was voided. Some more sleep.

On the third day, the figure was no longer gathered up as on the preceding evening. The patient was less disturbed; the symptoms presented by the tongue, pulse, and skin, were all favourable; the pain at the pit of the stomach was less severe. Lemonade and lavements continued, with half an ounce of castor-oil to each of the latter. The urine was copious.

On the fourth day the pulse almost natural, the tongue moistened, and the pains at the epigastrium less severe. Much eructation. The limb had lost none of its sensibility, contractility, or ordinary temperature. Two bouillons were given in the course of the day; lemonade and lavements, with frequent introduction of the sound. In the evening, the same state. Several hours sleep in the night, but interrupted with tiresome reveries.

The bandage being soaked through on the fifth day with suppuration, it was removed without any pain to the patient. A little black spot, about two lines in dia-

meter, was observed near the upper or external angle of the wound: this was probably owing to the compression of the spica. The aneurismal tumor was reduced to a third of its volume, and did not pulsate. The popliteal and posterior tibial arteries did not pulsate either, though they were evidently full. The slightest touch of the hand was felt over all the limb, and the heat, so far from being diminished, was rather augmented. The pain of the epigastrium was almost wholly gone; the other symptoms still lingered. The wound was dressed with strips of cerate and fine charpie, kept on by compresses and a triangular bandage. In the night, after much disturbance and some delirium, two emollient lavements took away a copious stool of black and consistent matter.

The sixth day was passed quietly, but on the seventh there was a slight accession of feverishness again. The wound, however, was healthy-looking, and the suppuration abundant. Remedies continued; bowels further relieved; some appetite experienced. On the eighth day the patient was going on very well. During the subsequent dressings the tumor was frequently observed to pulsate: it was quite sensible to the touch, but still more so to the sight when a fixed point was taken as a term of comparison on observing the tumor with close attention. Bowels continued open, and some sleep was enjoyed. There was now no longer any pain in the epigastric region, nor was the eructation any longer troublesome.

While dressing on the ninth day, some extremely strong pulsations were observed on the left side of the abdomen, a few lines above the wound: they were apparently belonging to the external iliac artery. The aneurismal tumor also presented pulsations still more distinct than usual; yet a diminution was every day taking place in its volume. The little black spot before-mentioned had now nearly altogether disappeared. A little *vin de Bordeaux* evening and morning. Hiccups were noticed between the tenth and twelfth days, frequent enough to interrupt sleep, but unattended by any other serious symptom. During the night of the twelfth day some pains of the limbs occurred, not very severe, but impressing the mind of the patient strongly enough to banish his hiccup.

The pulsations observed in the region of the external iliac artery had ceased on the fourteenth day. Those of the tumor were irregular and intermitting; the intermissions sometimes lasting for several seconds. On the sixteenth day the two ligatures came away together and of themselves.

On the twentieth day after the opera-

tion, the pulsations of the tumor were quite sensible to both touch and sight. The wound was dressed twice a day; the suppuration very abundant. Lavements every two or three days, to combat the habitual constipation of the patient. The angles of the wound began to cicatrize on the twenty-third day, and some fungous granulations were repressed by means of lunar caustic. Some streaks of blood were perceived this morning and evening among the pus in dressing; and towards night the first hæmorrhage was observed to have soaked the bandage. The quantity of blood might amount to about half a palette. On removing the bandage, every care was taken to ascertain whence the blood had flowed, but in vain: it had now ceased; so the wound was dressed as usual.

A second hæmorrhage ensued the next day, still more abundant than the first: it was attended with sharp pain in the wound. The blood was arterial, and seemed to come from the lower part of the wound. Compression with the index and middle finger of the right hand, an inch above the wound, had no effect: below the wound it suppressed the flow, and gave time to cleanse the parts from clots. A graduated compress was substituted for the fingers, and it was kept on by the elastic and circular bandage already mentioned: charpie was superadded. The figure of the patient was now altered, and the eructation once more came on.

The iliac artery, on being raised with a sound, could be distinctly seen, and might be compressed with the finger. Every time this was done the pulsations ceased in the tumor. It was eventually tied, and for six days after there was no recurrence of the pulsation. But in other respects, compression of this artery above the ligature had no influence in repressing the pulsations of the tumor: the blood which caused them came from a more distant source; in fact, by compressing the ventral aorta, they were fully checked. It was therefore clear that the blood did not come from the end of the artery which had been tied, but from vessels placed between the ligature and the ventral aorta: and what vessel could it be, unless it were the internal iliac artery, joined perhaps by the subternal?

But by what trunk was it that the blood was conveyed to the aneurismal sac? The femoral artery presented no pulsation below the tumor, and its compression appeared to increase rather than diminish it. Was it by the profunda? The position of this artery behind the tumor rendered it difficult to say. Was it, in fine, by the epigastric artery? The double communication of this vessel with the subternal and obturator is well known; nor is it a

rare thing that a very considerable arterial branch should extend from the one to the other of these arteries. This idea induced me to examine carefully the course of the epigastric artery, and it was with no small surprise that I felt strong pulsations along that course, even through the thickness of the abdominal parietes, and especially in the vicinity of the tumor. It hence seemed probable that the epigastric artery was the principal agent in restoring the pulsations to the tumor, and that in this case, as it sometimes happens after tying the primitive carotid, the very facility of communication, so far from favouring the cure, is the cause of the reproduction of the disorder. In the present instance, that facility had the additional inconvenience of giving rise to hæmorrhages that might prove fatal.

Every one knows the danger of consecutive hæmorrhages, and that with an equal or even a less considerable loss of blood, they are far more to be dreaded than primitive ones. Left to the efforts of nature, the latter would seem to lead to the death of the patient either immediately or by giving rise to some fatal affection. I was aware that a hæmorrhage, (much less serious than the present, it is true,) had terminated spontaneously in a patient operated on by M. Moulard: but I was also aware that another hæmorrhage had been fatal to a patient operated on even by Sir Astley Cooper himself. Now it was not my wish to abandon my patient either to the chance that saved the one or the misfortune that seized the other. But the difficulties which presented themselves to me were numerous. Did the blood come from the upper or the lower orifice of the artery? In the former case, the ligature having come off some time before, and the artery consequently having become retracted, it seemed almost impossible to effect the tying of it anew. It was, however, more probable that the hæmorrhage was from the lower end. Supposing this to be the case, it still remained to find a means of stopping it. Ought the lower end of the artery to be tied above the tumor?—but besides that this end was very short, which would render the ligature almost impossible to be fixed without cutting into the tumor, the said end would further be embedded in an inflamed cellular tissue, and thus participate in that condition which renders the coats of the vessels so divisible that the very best managed ligatures could not fail of cutting through almost immediately the parts to which they should be applied, and hæmorrhage would infallibly supervene. And farther, if the ligature were below the origin of the epigastric artery, the latter alone might keep up the

hæmorrhage by pouring out the blood which it received, to all appearance, from the internal mammary, or the obturator. Ought we to tie the trunk of the femoral artery below the aneurismal tumor, with a view to prevent the blood from returning by this artery to the tumor?—but here there was a doubt whether this was the source of the hæmorrhage; and, moreover, such ligature would be applied below the origin of the profunda. Now this, so far from arresting the hæmorrhage, seemed likely rather to increase it. In fine, ought we to open longitudinally the aneurismal tumor in the way usually adopted for operating on aneurism by incision?—in order to effect this, one thing was essentially requisite—namely, to be able to suspend the flow of blood into the limb during the operation. The blood, in fact, which would not fail to rush into the tumor by the epigastric artery, or the femoral itself, would infallibly render the operation dangerous. Former experiments had certainly shewn that it was possible to suspend, for the time, the flow of blood into the lower parts of the body by means of compression, exercised from left to right on the ventral aorta: but besides that the contraction of the muscles occasioned by the pain, the least motion on the part of the patient, or the least hesitation in the assistant, could deprive us altogether of this resource, it appeared very difficult to proceed to tie the epigastric, the profunda, and the femoral itself, in the very tumor, without extreme risk. Such were the reflections which induced me to abandon the idea of ligature and to employ compression, which, though less certain in general than ligature, gave some security against the danger which the latter might occasion.

But in order that the compression should be efficacious, it should be so managed as that it should bear precisely on the point which gave issue to the blood; and the difficulty was to find that point. For this purpose, I renewed my attempts at compression both above and below the wound: the former allowed the blood to flow, the latter invariably stopped it. The blood, therefore, came from the lower, not the upper end, and consequently it was clear which part ought to be compressed. This compression, besides, having nothing more to subdue than an effort which was already much diminished by the anastomoses, seemed to present no small chance of success.

Scarcely had an hour and a half elapsed when the hæmorrhage appeared for the third time; the bandage, however, was scarcely stained: the compression was augmented, and the hæmorrhage once more suppressed. In the course of an

hour, the compression being relaxed, there was a fourth flow of blood, which was suspended as before; but the compression bore heavily on the patient. The lower margin of the wound was sunk, the upper elevated about half an inch above the cushion of the bandage, and the thickness of the latter was full half an inch; so that the matter was critical. Was it to this that the extraordinary and unexpected return of the pulsations and of the repeated hæmorrhages was to be attributed? I mean, was it to be attributed to the promptitude and facility with which the flow of blood was re-established below the ligature? What else could it be that occasioned the renewal of the pulsations on the sixth day, and of the hæmorrhages which came on eight days after the fall of the ligatures, and twenty-three after the operation.

Upon removing the bandage and cleansing the wound, three clots of hardened blood were extracted from it, when immediately a flooding ensued; but it was staunched by the application of the fore finger of the right hand. So speedily was this obliged to be done, that there was no opportunity of ascertaining exactly whether the hæmorrhage really came from the lower orifice of the artery, as we were previously led to believe. But by suspending the compression for a second, a little blood was seen to flow from the lower orifice. During these experiments, pledgets sprinkled with powdered rosin were prepared, and on the removal of the finger one of them was placed in the bottom of the wound. Other pledgets were then successively put over the first, and the wound being thus exactly filled, a thick and triangular-shaped compress was laid over all. The patient bore all this tolerably well. The leg and thigh were then flexed upon the pelvis, and maintained in that position by a cushion placed under the ham.

On the twenty-fifth day it was perceived that there had been a large flow of blood on the inner side of the spica of the groin, though the bandage was not altogether penetrated by it. Pledgets of charpie were applied, and kept on by a new spica. The day following a large exudation of blood and pus took place between the skin and the bandage, and the abdomen was tender for some inches round the spica of the groin; but the inconvenience soon subsided.

A fifth hæmorrhage occurred on the thirtieth day, and arterial blood was observed to flow along the scrotum; it was arrested like the previous ones, and it was the last that occurred.

A few days after, part of the bandage was removed, and little more was left than the tampons in the wound; the margins of

the latter were red, and excoriated in some parts; they were dressed with cerate, and set to rights.

Nothing very important occurred till the thirty-sixth day, when it was observed that the tumor was soft and flabby; it might be touched without causing pain; a deep fluctuation was noticed in its middle and upper portion. Was this an abscess, or a sanguineous effusion owing to the rupture of the aneurism? If it was the former, it ought to be opened; if the latter, would it not be exposing the patient to fresh hæmorrhage by making an incision? From the previous symptoms it was judged that the former was the safer proceeding; and accordingly a bistoury was plunged into the part. Nothing but a little sanies was at first discharged; but by pursuing the puncture with pressure, an abundance of the same matter, mixed with a little very thick pus, was brought away. The part was dressed twice a day, and for some time a large quantity of pus was discharged; the patient meantime being kept on decoction of kina and wine and water.

From the forty-second to the forty-eighth day the convalescence of the patient seemed established; yet, as he was in low spirits, and likely to be affected with fever if there were not some immediate change, it was judged proper to transfer his residence to one of the most bustling quays of the capital, and to alter his diet and mode of life. In eight days the wound became cicatrized, and he was soon able to move about. Thus, after about two months of serious and threatening accidents, Berger was at last pronounced to be perfectly cured.

Three years after the operation the limb was in no wise altered in volume or shape, and was as nearly as possible as strong as the corresponding member. Neither the heat, sensibility, or muscular motivity of the part, was in the least degree altered. In the circulation there was nothing remarkable. The patient used frequently to go several leagues on foot, and pursued his daily occupations without trouble or fatigue: he had even gone a journey of above forty leagues without inconvenience. There was, however, a feebleness of the walls of the abdomen about the place of the operation; and on this account he was obliged to wear a belt.

In the year 1827, eleven years after the ligature of the iliac artery, Berger was in the most satisfactory condition, and there was nothing in his case to detract from the completeness of the cure: he still went on with his toilsome trade of a mason.

The details which I have here given render any additional supplementary remarks superfluous; I shall only observe, that the two operations here described,

together with that which I have in like manner practised on the primitive carotid, sufficiently show the immense resources that we at this day possess in the treatment of aneurisms, which have been until a comparatively recent period deemed perfectly incurable.

ON A PARTICULAR CLASS OF MUSCULAR MOVEMENTS.

In a Letter from M. CHEVREUL to M. Ampère.

YOU require of me a description of the experiments I made in 1812, to know whether it be true, as several persons assured me, that a *pendulum, formed of a heavy body and a flexible cord, oscillates when held in the hand over a certain body, though the arm be not moved*. You consider these experiments to possess some importance. On yielding to the reasons which you gave me for publishing them, be it allowed me to say, that I had need of all the dependence which I have in your sagacity, to come to the resolution of placing before the public facts of a description so different from those which I had been hitherto in the habit of submitting to it.

The pendulum I used was an iron ring from a hempen cord: it had been arranged by a person who was very desirous that I should myself verify the phenomenon which displayed itself, when suspended over water from a block of metal or a living being—a phenomenon of which he made me a witness. It was not, I own, without surprise that I beheld it reproduced, when having myself seized with my right hand the thread of the pendulum, I placed the latter over the mercury of my pneumatic tub, over an anvil, and also over several animals, &c. I concluded from my experiments, that if there was, as they assured me, but a certain number of bodies calculated to produce the oscillations of the pendulum, it might happen that on interposing other bodies between the former, and the pendulum when moving, the latter might be stopped. Notwithstanding my previous opinion, my astonishment was great, when, after having taken with my left hand a plate of glass, a cake of resin, &c. and having placed one of these bodies between the mercury and the pendulum which oscillated over it, I perceived the oscillations to diminish in extent, and to be destroyed altogether. They recommenced when the intermediate body was withdrawn, and were again destroyed by the interposition of the same body. This succession of phenomena was repeated a great many times with a very remark-

able constancy, whether the intermediate body was held by myself, or by any other person. The more extraordinary these effects appeared to me, the more I felt the necessity of verifying whether they were really foreign to all muscular motion of the arm, as had been stated to me in the most positive manner. This led me to rest the right arm, which held the pendulum, on a wooden support, which I caused to advance at pleasure from the shoulder to the hand, and to return from the hand to the shoulder. I soon remarked that in the former case it decreased in proportion as the support approached nearer to the hand, and that it ceased when the fingers which held the cord were themselves supported; whilst in the second case, the contrary effect took place. From this I thought it very probable, that a muscular motion which occurred without my knowing it caused the phenomenon, and I could not but attach importance to this consideration, inasmuch as I had some vague recollection of having been in a very particular state, when my eyes followed the oscillations described by the pendulum which I held in my hand.

I repeated my experiments, the arm perfectly free, and I was convinced that the recollection just now mentioned was not an illusion, for I clearly perceived that at the same time that my eyes followed the pendulum which oscillated, there was in me a *disposition or tendency to motion*, which, involuntary as it seemed to me, was satisfied in proportion as the pendulum described greater arcs: thence I imagined, that if I repeated the experiments with the eyes covered, the results might be altogether different from those which I observed. This is precisely what happened. Whilst the pendulum oscillated over the mercury, a bandage was placed over my eyes: the motion soon diminished; but though the oscillations were feeble, they did not suffer sensible diminution by the presence of the bodies which appeared to arrest them in my first experiments. Finally, setting out from the moment when the pendulum was at rest, I held it for a quarter of an hour over the mercury without it resuming its motion, and at this time and always, without my knowledge, either the plate of glass or the cake of resin was interposed.

I interpret the phenomena in this way. When I held the pendulum in my hand, a muscular movement of my own, though insensible to myself, caused the pendulum to quit its state of rest, and the oscillations once commenced were soon increased by the influence which the sight exercised in putting me into this particular state of *disposition or tendency to motion*. Now, it must be acknowledged, that this muscular move-

ment, whilst it is increased by this same disposition, is, however, feeble enough to be arrested; I do not say under the dominion of the will, but when one has merely *the thought of trying if such a thing will arrest it*. There is then an intimate connexion established between the performance of certain motions, and the act of thought relating to it, though this thought may still not be the will which commands muscular motions. It is in this that the phenomena I have described appear to me to be of some interest in physiology, and even in the history of the sciences: they prove how easy it is to take illusions for realities every time that we are engaged in phenomena in which our organs take a part, and that in circumstances which have not been sufficiently analyzed.

Accordingly, let me be confined to make the pendulum oscillate over certain bodies, and to the experiments in which these oscillations were arrested when glass or resin was interposed between the pendulum and the bodies which seemed to cause its motion, and certainly I could have no reason not to believe in the divining wand, or any other thing of the same kind. Now, it will be easily conceived how men of credibility, and otherwise of enlightened minds, are sometimes induced to have recourse to ideas entirely chimerical for the purpose of explaining phenomena which in reality do not spring from the physical world with which we are acquainted*. Once convinced that nothing truly extraordinary existed in the effects which had caused me so much surprise, I found myself in a disposition so different from that in which I was the first time I observed them, that long after, and at different periods, I tried to re-produce them, but always ineffectually.

In calling your testimony to a fact which passed before your eyes twelve years since, I shall prove to my readers that I am not the only person on whom sight has had influence in determining the oscillations of a pendulum held in the hand. You remember, no doubt, that when at your house with General P—, and several other persons, my experiments became one of the subjects of conversation; that the General expressed a desire to know

the particulars of them, and that after they were explained to him, he denied not how the influence of sight on the motions of the pendulum was contrary to all his ideas. You recollect that on my proposing to him to perform the experiment himself, he was struck with amazement, when, after having put his left hand on his eyes for some minutes, and then withdrawing, he saw the pendulum which he held in the right hand absolutely motionless, though it was oscillating rapidly at the moment when his eyes had ceased to see it.

The preceding facts, and the explanation I have given of them, led me to connect them with others which we may observe every day; by this connexion, the analysis of these becomes at once more simple and more precise than it had been, at the same time that there is formed an aggregate of facts, the general explanation of which is susceptible of considerable extension. But before going farther, let us remember that my observations present two principal circumstances:—

1st. To think that a pendulum held in the hand can move, and that it moves without the individual being at all conscious that the muscular organ impresses on it any impulse: *that is the first fact*.

2dly. To see a pendulum oscillate, and that its oscillations become more extended by the influence of the sight on the muscular organ, and always without there being any consciousness of it: *that is a second fact*.

The tendency to motion caused in us by the sight of a body in motion, is ascertained in several cases; for example—

1st. When the attention being entirely fixed on a bird flying, on a stone cleaving the air, on the water that flows, the body of the spectator is directed more or less towards the line of motion.

2dly. When a person playing at ball or billiards, following with the eye the moveable body on which he has impressed the motion, he carries his body in the direction which he desires the moving substance to follow, as if it were possible even still for him to direct it to the mark which he wishes it to reach.

When we walk on a slippery plain, every body knows with what readiness we throw ourselves from the side opposite to that to which our body is drawn in consequence of a loss of equilibrium; but a circumstance less generally known, is, that a tendency to motion manifests itself even when it is impossible for us to move in the direction of this tendency; for example, in a carriage, the fear of being upset inclines you in the direction opposed to that with which you are threatened, and thence there result efforts so much the more painful as the fright and irritability are greater. I think that in ordinary falls, letting one's

* I can very easily conceive, that a man, whose entire attention is fixed on the motion which a rod that he holds in his hand may assume, by reason of a cause unknown to him, can receive from the slightest circumstance the *tendency to motion* necessary to develop the phenomenon with which he is engaged: for example, if this man is going towards a spring, and if his eyes are not bandaged, the view of the spacious green turf on which he walks may cause in him, without his knowledge, the muscular motion capable of disturbing the rod, by the connexion established between the idea of active vegetation and that of the water.

self fall (*le laisser-tomber*) has less annoyance in it than the effort to prevent the fall. It is in this way I understand the justice of the proverb, "there is a God for children and for drunkards."

The fact I have just mentioned naturally leads to the case, where being placed on the summit of a mountain, the breadth of which presents a passage much broader than would be strictly necessary if we were going along the high road, we come all of a sudden to discover the depth of an abyss placed below us; at the same moment, if I may so say, we throw ourselves irresistibly from the side opposed to the abyss, impelled by the instinct of self-preservation, which struggles against a tendency to move in a contrary direction, caused by the sight of the abyss. This tendency is still more remarkable when we are on a bridge without railing, placed over a precipice: this precipice, viewed from one side of the bridge, makes you throw yourself towards the opposite side, and puts you in the same state of anxiety as that from which you desired to withdraw yourself. Thus distracted successively in two opposite directions, you become stupified and motionless, if even the excessive fear of falling on the side where you are does not make you encounter the danger of throwing yourself on the opposite side. Such, in the case now before us, is the position of a man who has not been accustomed to walk on a narrow road suspended over an abyss, whilst the man who has been used to it walks as firmly as on the high road, because that, being free from fear, he thinks not of the danger which the former dreads. In fine, the position of the latter might become more critical still, if he were led to discover the depth of the abyss in the case, where following with the eye the flight of a bird, or the throw of a stone, &c., he had already obeyed to a certain degree this tendency which carries us towards a moving body.

The tendency to moving in a certain direction, resulting from the attention given to a certain object, seems to me the primary cause of several phenomena generally referred to *imitation*; thus, in the case where sight, and even hearing, direct our attention to a person who yawns, the muscular motion of yawning is ordinarily the consequence. I might say the same of the communication of laughing; and this very example presents, in a very particular manner, a circumstance which seems to me strongly to support the explanation I give of these phenomena; it is, that laughing, at first weak, may, if prolonged, become *accelerated*, pardon me the expression (as we have seen the oscillation of the pendulum held in the hand increase in extent under

the influence of sight), and laughing, thus *accelerated*, may proceed even to convulsion.

I doubt not but that the sight of certain actions calculated to make a strong impression on our feeble frame, that the recital of these same actions animated by the voice and gesture, or, still more, the knowledge which persons acquire by merely reading them, do incline certain individuals to these same actions, by reason of a tendency to motion which determines them thus mechanically to an act of which they never would have thought without a circumstance foreign to their will, and to which they never would have been led, by what is called *instinct* in animals.

The great actor is he whose gesture, and the movements of whose countenance, correspond to the movement which the sentiments that he introduces on the stage should excite in the character he represents.

The historical painter, who has studied nature, seizes the position which the originals of the persons he paints should have, when they concurred to the act which the pencil should reproduce.

The great poet is he whose verses awaken in those who hear him emotions corresponding to the actions which he sings; such is the recital of a portion of the *Iliad* which impelled Alexander to buckle on his arms.

In concluding here the exposition of the facts which appear to me to be connected with my observations, I think it right to make a remark, which is implied in what I have said, but which may escape some reader: it is this, that this tendency to movement, to which I refer the primary cause of a great number of our acts, takes place only when we are in a certain state, which is precisely that which magnetizers call *faith*. The existence of this state is perfectly demonstrated by the recital of my experiments; accordingly, as long as I believe in the *possibility* of the motion of the pendulum which I held in my hand, it took place; but after I discovered its cause, it was no longer possible for me to re-produce it. It is because we are not always in the same state that we do not always receive the same impression from the same thing: thus, the yawning of another does not always make us to yawn; laughing is not always communicated from the laugher to his neighbour. The great orator who wishes to impart to the listening crowd the passions that he himself feels, does not arrive at his destination at once: he begins by predisposing his audience, and it is only after he has made himself master of this that he draws forth his strong arguments. The great poet, the great historian, constantly use

the same artifice. They first prepare their reader to receive the final impression. Nothing is more curious, in the study of the causes which determine human actions, than the knowledge of the means employed by the merchant, first to call and then to engage the attention of the buyer to the qualities of the object which he wishes him to take; than the knowledge of the means employed by the juggler, in order to draw from the pack such a card rather than any other, or to direct the spectator's attention to some certain thing, for the purpose of distracting it from some other—a distraction without which the juggler could not cause the surprise, which is the final aim of his art. From these considerations it results, that professions the most opposite employ means altogether analogous, though exceedingly varied, to arrive at the same end—that of first securing the attention of the individual, in order afterwards to produce on him a determinate effect.

I think that my observations are connected with the history of the faculty of animals—that there are some of their actions attributed to instinct, which enter into the class of those of which I have spoken. It is particularly in animals which live in groups that it would appear to me to be interesting to study the influence of the chiefs over the subordinate individuals. In fine, do not the facts I have stated throw some light on the cause of the *fascination* which one animal makes another experience?

I think that my observations should also engage the attention of the physiologists, who, like M. Flourens, have examined in a particular manner the movements which supervene in animals after the removal of certain parts of the nervous system; it would seem to me to be important to appreciate the influence which the removal of such a one of these parts could effect on the developments of the phenomena which constitute the subject of this letter.

Such are, my friend, the subjects which you have considered may be interesting to persons, who think with us that the course to be followed in physiology is that which has been traced out by the men to whom the natural sciences owe their advancement, and who share in our opinion that there are no positive metaphysics for him who is ignorant of the great truths of the physical and mathematical sciences. The study of the faculties of man is invariably connected, not only with the knowledge of the means which he has employed in order to establish each of the special branches of these same sciences, but the same holds good also with respect to the knowledge of the faculties of animals. Before seeking to

draw up a general system of philosophy, we must collect as large a number, as is possible, of groups of analogous facts; and, besides, it is necessary that the facts of each group be previously examined into with particular study.

E. CHEVREUL*.

COW-POX AND SMALL-POX CO-EXISTENT.

To the Editor of the Medical Gazette.

SIR,

IN a late number of the Medical Gazette I observed a letter from Mr. Brown, of Musselburgh, disapproving, in strong terms, of the practice of vaccinating to prevent variolous contagion.

The importance of the subject at the present crisis, will justify my trespassing on a small space of your valuable journal. I have, within the last two months, had opportunities of noticing many cases of small-pox, which have occurred in the practice of my uncle, Mr. Selwyn; the variolous epidemic having been prevalent here.

The greater part of the cases (occurring in persons who had not undergone vaccination) were very severe, and of the confluent kind; while those after vaccination were uniformly mild, producing scarcely any constitutional disturbance, with a very trifling quantity of the pustular eruption: but I wish particularly to direct your attention to the following case.

On the 17th of August last I vaccinated Ann Mayo, aged thirteen months, while suffering under a commencement of the pyrexia and other usual precursory symptoms of variola; of which pustules began to make their appearance on the 19th. The cow-pock was at the same time pursuing its usual course, and effectually succeeded in subduing its opponent; for on the 24th (seven days from the time of vaccination, and five from the first appearance of the variolous eruption) there were two perfect vaccine vesicles, and the small-pox pustules, which had not been very numerous, were dying away. As I do not recollect ever meeting with so decidedly satisfactory a proof of the efficacy of the Jennerian

* Archiv. Gen., May 1833, and Dublin Journal.

discovery, I shall feel myself greatly obliged by your giving it publicity; at the same time allow me, through the medium of the *Medical Gazette*, to express my gratitude to the Board of the N. V. E. for the very prompt and liberal attention which has always been paid to my applications for lymph. I beg leave to subscribe myself, sir,

Your obedient servant,

W. S. MORRIS.

Sedbury Dispensary, Sept. 9, 1833.

HYDROPHOBIA.

To the Editor of the Medical Gazette.

SIR,

IF the following may be considered a case of rabies resulting from the bite of a dog, then I think it possesses some features of interest: at all events, I take the liberty of submitting it to you for publication.

— Ames, the son of a publican, about fourteen years of age, was bitten, three months ago, by a dog; which, suspected of being rabid, was immediately after killed. I ordered the bitten part to be cut out, but the man chose to submit his son to a peasant of *medical repute*, who took 3*l.* 5*s.* for giving him some physic and pronouncing him cured. On Monday, the 2d inst. the boy complained of uneasiness in his throat, and a sense of suffocation; at the same time he seemed very anxious, spoke much of death, and said he had heard of "people's throats closing up," and that he believed *that* would be his end. On Tuesday this anxiety and apprehension increased, without the appearance of any other illness. On Wednesday, at three o'clock, when I first saw him, he was in a state of extreme agitation, gasping and panting for breath like one suddenly immersed in the sea, and suffering from the consequent shock and alarm. His eyes were wild, and expressive of the extremest anxiety; the pupils dilated. He was constantly spitting. He seemed to have a strong desire to cool his mouth with water: when it was given to him, his agitation was increased; he seized the vessel, sipped it, and then seemed violently convulsed, and struggled still more for breath. Still he would hold the vessel, exclaiming, "a little at a

time!" and this exclamation he constantly repeated. When asked a question, he would reply in an eager and interrupted way, as if he could not spare breath for utterance. He said he had no pain, except slight, with a feeling of coldness, on the back of the head; but holding his bitten hand up to my face, he said, "Look there, sir; look there, sir!" On presenting a candle to the eyes the pupils did not contract, and the boy was much frightened by the increased light. All noise, especially the breaking of the waves on the beach outside the window, brought on extreme agitation. He would look round as if pursued, or afraid of somebody's approach. The spitting was continued, interrupted only by occasional vomiting and abrupt exclamations of alarm. Pulse 130, small.

The treatment—a warm-bath, with cold on the head, belladonna rubbed on the throat, a suppository of three grains of opium (an anodyne by the mouth was rejected)—had no effect. The wildness increased until it amounted to violence and delirium, and the patient died within four hours after the time that I first saw him. On examining the head the next day, the only morbid appearance was vascular turgidity, and the brain throughout was softer than natural. In the larynx and upper part of the trachea there was no appearance of inflammation, or appreciable lesion.

If this was a case of rabies, it goes, with another somewhat similar, which I saw when clerk in the Edinburgh Infirmary, towards proving that *hydrophobia*, apart from the dread of spasm produced by swallowing the water, is not an essential symptom of the disease.

This case is, perhaps, interesting also, considering the length of time that elapsed between the application of the cause and its result, and likewise on account of its rapid progress.

I have the honour to be, sir,

Your obedient servant,

W. TRAVERS COX, M.B.

Great Yarmouth, Sept. 7, 1833.

IMPROVED TRUSS.

To the Editor of the Medical Gazette.

SIR,

MANY instruments have been projected to obviate the inconvenience and danger

arising from hernia. I have found none so applicable to double *inguinal* hernia as an improvement I made upon Law and Oddy's patent double *inguinal* truss.

I discovered, upon examination, that Law and Oddy's truss produced its pressure above the site of the point of protrusion; therefore I removed the two anterior pads, and in their stead constructed two iron extremities, the shape and size of the common truss, which were firmly rivetted to the anterior extremities of the patent truss, and padded as usual. A soft silk handkerchief being placed between the truss and the integuments will materially diminish the friction. I feel assured that this improved truss will answer a better purpose than any I have seen; which induces me to request the insertion of this notice in your Gazette.

I am, sir,

Your obedient servant,

JOSEPH CHIPMAN.

Picton, Nova Scotia, America,
August 15, 1833.

This communication is from one of your admiring subscribers, and will be conveyed by the Royal William; which will be the first steam-vessel that ever will have crossed the Atlantic.

MOTION OF THE LIMBS, AND INCREASE OF TEMPERATURE,

AFTER DEATH FROM CHOLERA.

To the Editor of the Medical Gazette.

SIR,

I WAS called a few days ago to witness the last four hours of the departing life of a patient in cholera, who, on the preceding day, had been in unusual spirits and good health, until very painfully impressed by mental disturbance. The same evening a diarrhoea, very copious and fluid, came on, the colour of which did not happen to be seen. His night was a little disturbed; but he arose at six in the morning, and travelled fourteen miles, having been well enough to enjoy the beauties of his early ride. He was compelled by a return of symptoms, and extreme debility, to solicit a reception at an inn on the road, where he experienced great kindness from his host, and unceasing attention from a judi-

cious and zealous practitioner. His disease was rapid; remedies availed nothing; and in twenty-four hours from the first symptoms he had expired, having had the pale evacuations, the spasms, and strongly-marked blue colour, with cold arms, humid with sweat.

About half an hour after his death, *i. e.* the perfect termination of respiration and circulation, a friend observed his left arm to move, and very soon it obeyed the contractile and relaxing powers of its muscles, slowly but unceasingly, for about twenty minutes; it then ceased, and the right arm soon made an extensive motion, which threw the bystanders into a panic. Contraction and relaxation, or a moving backwards and forwards, continued perhaps to the end of an hour and a quarter. At this moment the arms, previously cold, had become evidently warmer.

I offer this case, not for the sake of any interest which it can afford for novelty of treatment, or success of practice, but to take the opportunity of shewing the apparent probability, that a strong mental depression is capable of exciting the disease, when the mysterious principle pervading the country has infused a general predisposition into the population; and to remark, therefore, on the possibility of sometimes preserving freedom from it, by a careful discrimination, and avoiding the circumstances which experience shall discover to be capable of exciting the disease.

The town in which this gentleman resided, I understood, was free from the disease, and that it had not been heard of in the part through which he passed, or at which he died.

The increase of temperature which took place after death, and which I have before observed in a more remarkable degree than in this case, may, I think, admit of explanation. During the declining powers of the patient, and the imperfect oxygenation of blood which happens in cholera, the animal heat is feebly evolved, yet rapidly carried off by the high conducting principle of evaporation, which the copious exudation of sweat keeps up. To some depth, therefore, the limbs are kept very cold. After death there is no succession of perspiration; and as soon as the limbs are dry, I conceive the conducting principle, common to matter, leads to the more equal diffusion of heat from within, throughout its substance, whilst it ceases

to meet with the more rapid exhalation from the surface by watery particles, and is of necessity obvious to examination.

If the preceding is worthy a place in your valuable journal, I shall be much obliged by its appearance; and am, sir,

Your very obedient servant,

NATH. RUMSEY,

Member of the Royal College of Surgeons
of London.

Beaconsfield, Sept. 14, 1833.

ACCOUNT OF A CASE

IN WHICH

A FEMALE CATHETER ACCIDENTALLY SLIPPED INTO THE BLADDER,

In Drawing off the Water.

BY JONATHAN TOOGOOD, ESQ.

Senior Surgeon to the Bridgwater Infirmary.

DURING the last year I was requested by a medical friend to meet him in consultation on a case, where he had permitted a silver catheter to slip into a lady's bladder. The patient had had a few weeks previously a severe labour, producing paralysis of the bladder, and rendering the introduction of the catheter necessary night and morning. A few hours before my visit, her medical attendant, in attempting to draw off the water, experienced some difficulty, and whilst making more pressure than usual, the catheter slipped into the bladder. He immediately attempted to reach it with his dressing forceps, but failed.

I advised him to wait until it became necessary to draw off the water again, then pass a longer catheter, and endeavour to discover its position; but it could not, however, be detected, and the operation was repeated several times before it was felt.

The following plan was then tried:—A piece of sponge tent, somewhat longer than a common female catheter, and of the size of the little finger, was passed into the bladder, without difficulty or giving pain, and allowed to remain eight or ten hours, during which time the water passed freely through it. At the end of that period it was removed, and the fore finger of the left hand passed readily into the bladder. The catheter

was felt lying across, one end resting on the pubes, and the other imbedded in the folds at the back part of the bladder. There was considerable difficulty in bringing it into the urethra, which was effected by carrying the fore finger of the right hand into the vagina, and pressing the bladder backwards and upwards, which brought that part of the instrument lying over the pubes within reach of the other finger, and then into the urethra, from whence it was readily removed by the dressing forceps. All this was effected with very little pain, and without the patient or her friends even being aware of what had happened. The instrument, which was one of the sliding short catheters recommended by Mr. Jewel, remained in the bladder fifteen days, producing but very slight irritation.

This is, I believe, a very rare accident; and on looking at the catheters which are generally in use, one only feels surprised that it does not happen more frequently, as there is not sufficient guard to prevent it. Mr. Abernethy used to relate in his lectures a case of this kind, where the catheter was not extracted; and a long time afterwards an abscess formed in the side, which was opened and discharged freely for some days, when, on passing a probe, a hard substance was felt, and extracted with a pair of common forceps, which proved to be a catheter.

Sir Astley Cooper lately obligingly shewed me a drawing of a calculus formed over a catheter which had got into the bladder, and which he removed by the usual operation some years since at Guy's Hospital. To this gentleman I am indebted for suggesting the plan which proved so successful in this case.

I observed in this case that the whole internal lining of the vagina was in a sloughing state, which I think very frequently occurs after laborious parturition, where the head rests for many hours in the vagina. Although I do not remember to have seen it noticed, much of the soreness and pain which women complain of after such labours arises, in my opinion, from this cause, and would probably lead to adhesions, if nurses did not use the precaution of smearing the parts frequently with ointment.

PRUSSIC ACID—REPLY TO MR.
PHILLIPS.

To the Editor of the Medical Gazette.

SIR,

I TRANSMITTED to the Medical Gazette of August 10th, a formula for preparing perfect and cheap prussic acid, by the extemporaneous decomposition of cyanuret of potassium by means of tartaric acid. In your No. for last week (Sept. 14th) are some remarks on that communication by Mr. Richard Phillips, and which supply me with occasion so soon again to trouble you.

Mr. Phillips has referred me to two journals, as containing proof "that this very method has been already adopted and described by Mr. Clark, of Glasgow." On turning to those journals I find, indeed, the very paper which first led to my discussion of the subject with Mr. Clark, but nothing which induces me to believe that the method there *described* was ever successfully *adopted* by that gentleman. Indeed, before Mr. Clark could possibly adopt his own suggestion, he must have possessed himself of the cyanuret of potassium; and I have no apprehension of being corrected, notwithstanding the respectable authorities cited by Mr. Phillips to shew its easy practicability, when I assert, that Mr. Clark's method is totally inadequate to the production of the cyanuret in a state even approaching to purity. It is singular enough that, while I am censured for avoiding mention of Mr. Clark's name in my brief announcement in the Medical Gazette, I should in a contemporary journal of the same date make a distinct allusion to his process as a complete failure. It is not, however, a sin on the part of Mr. Phillips, that he conceived the one paper which he read to contain all that I had ever written on the subject; but it is a felicity for me to have transmitted for his perusal a lately printed document, and also to be able to refer him to others in the Lancet for May 21, June 25, July 9, and July 30, 1831,—in all which, instead of concealing Mr. Clark's name and performances, I shall be found to have placed them prominently forward.

Mr. Phillips has taken an objection to the term *delicacy*, as applied to the cyanuret of potassium, and courteously

presumes it to be a misprint for *imperfection*. He will pardon me if I waive the proffered emendation, and avow still a predilection for my own expression; for I know not how better to describe, in one word, that extreme feebleness of the affinities which alone can prevent the elements of the salt from forming new combinations, and which has hitherto sufficed to render the task of procuring it one of no ordinary difficulty.

With regard to the composition of the salt, I have stated that I *proved* it to be cyanogen 3.25 + potassium 5 = 8.25. Mr. Phillips implies, that to preclude suspicion of borrowing those numbers, it would have been only prudent had I given the details of my analysis. I am quite sure Mr. Phillips himself would be the last person to entertain such a suspicion, or it would attach to every chemist who has quoted the same numbers without detailing his experiments, especially as not one beside myself (so far at least as I am aware), has hinted at having submitted the cyanuret of potassium to analysis. Of course the numbers are easily to be assumed from the theory of equivalents; and when, in the absence of all pretension to the contrary, I have found them written in systems of chemistry, I have taken it for granted that they were so assumed. Under this conviction I spoke of *proof*; and when I add, that the analysis on one occasion was made in company with Dr. Granville, I shall be excused for having avoided, in a medical publication, a strictly chemical calculation, which, Mr. Editor, you know is sufficiently distasteful to the generality of professional readers.

I am glad that Mr. Phillips arrives at the conclusion, that "the plan is probably destined to supersede the uncertain methods now in use;" for so, of course, I understand him, since he thus quotes from me without any expression of dissent from the opinion. Alas! sir, I had almost said *my* opinion; and I must confess, that this self same thought has appeared in print ever since May 1831. I recollect reading about this plan, that "it is exceedingly elegant and effectual, and must entirely supersede all the processes adopted for the preparation of this energetic medicine." People who study much will stumble sometimes over some out-of-place odd volume; and who can tell but Mr. Phillips, in turning over

leaves of the old medical journals, might have discovered in this fresh occasion to correct me for tripping.

I am, sir,

Your obedient servant,

RICHARD LAMING, M.R.C.S.

43, Finsbury Square,
Sept. 17, 1833.

SELF-SUPPORTING DISPENSARIES—LETTER FROM MR. SMITH.

To the Editor of the Medical Gazette.

SIR,

I HAVE been obliged, by a friend in the north, with a copy of the memorial presented by the medical gentlemen of Sheffield to the Governors of the Dispensary in that town.

I rejoice to see it: it is a temperate and judicious remonstrance against the admission of improper persons to the benefit of the Sheffield Dispensary. Perhaps you will favour your readers by copying it in your journal*.

It is now nearly twenty years since I read a lecture on the misapplication of charity; intending to prove that, in proportion as we gave certain fixed and periodical assistance, we destroyed the *prospective feeling*, and that this feeling constituted one of the distinctive characters between man and the "brutes that perish." A part of this lecture I have introduced in the one that proposes a remedy for the various evils of poverty, sickness, and old age; and which I have since repeated at Leicester, in 1826, and at Derby, Gloucester, Worcester, and other towns. After detailing the evils of contracting for the poor in sickness to the parish surgeon, I go on to say, "But I may be told there are hospitals and dispensaries in abundance, for administering gratuitous relief, and supported too, with a liberality that reflects imperishable honour on our character as a nation. True: but these institutions are necessarily confined to the larger and more opulent towns, and embrace but very partially within their beneficent operation large districts where the population is thinly scattered, and where the number of the rich is sadly limited; indeed, in the largest towns,

where they are best supported, they can never meet all the cases that must arise in a poor man's family. They are *useful to the public only as schools of medicine*, and when not used for that purpose are oppressive to those excluded, by creating a monopoly in behalf of a favoured few. Neither are the sick poor always inclined to avail themselves of the relief which hospitals or dispensaries afford when most readily accessible; and the honest English poor never will, and they certainly *ought not to be taught*, to do so, unless they are permitted to contribute their mite towards the expense.

"I will observe, but not dwell on, the natural aversion of the English poor (a country day-labourer, for instance, or a well-informed town mechanic) to hospitals supported solely by the rich as places of experiment; for this may be sometimes an affectation, sometimes a prejudice. It is only when their sense of honest, manly, self-independence, is become seriously impaired by the operation of the poor-laws, or when they cannot have an equal hope of cure by the employment of the private practitioner, that they resort, without scruple, to these or any other charitable institutions.

"The first wish and endeavour of every Christian is to 'provide for his own household:' he knows that if he neglects to do this he has denied the faith, and is worse than an infidel; and every country day-labourer naturally does this, whenever he has not been vitiated by contact with the overseer, the denationalizing habits of pauperism, or more debilitating reliance on the charity of the idle and silly rich who give, without inquiry, and may and will go on giving till they have nothing left to give. The first wish of an honest man is to pay for his health, as he does for his food and raiment; he likes to choose his own doctor, and such choice is in itself medicinal; and he feels a manly satisfaction in striving to pay, out of his own earnings or his scanty store, for the skill and attention which his case (always to him a most important one) requires.

"I entreat the authorities in this district to take advantage of this honest pride wherever it may be found, and to encourage it: it is more general than is suspected—if out of sight, it is but dormant, and may be roused and trained to any thing; for even when such a man passes by the regular practitioner, and

* The document will be found at the close of this letter.

has recourse to the nostrums of the quack, (and hundreds of thousands are expended by this class in quackery,) it is originally rather by a feeling of necessity than any other inducement that he is usually actuated, being resolved not to incur a doctor's bill, which he can never hope to pay. One can hardly forbear shedding a tear over the self-denial and forbearance which these doctors' bills occasion if they are paid; for the honest poor man and the doctor, 'whose poverty, not his will, consents,' alike deserve commiseration. Who living by the labour of his hands would not desire to escape from this bill? The doctor hates his own bill!

"A sturdy English labourer *resolves not to incur such a bill*; and yet, instinctively anxious to husband out 'life's taper to its close,' he seizes with avidity on what is so temptingly recommended in the County Chronicle—is so readily obtained at a respectable stationer's, whatever the drug may be: he hears the stationer, or grocer, or druggist, is a good sort of man, and he reads with delight that a few shillings' worth will produce total renovation. Such a man flies to the empiric only when *too poor* to pay the man of education and science. Alas! it were far better, for himself at least, that he should at once fall upon the parish, and obtain the advice of the regular practitioner, as he may, than that he should thus purchase poison for the sake of its cheapness. Miserable, degraded, wretched, cursed, desperate, as is a state of dependence on any man for any thing that is necessary to one's comfort and life, or the life and comfort of one's wife and little ones, and almost hopelessly desperate as is the state of parish pauperism and dependence, there is still a possibility of redemption from it; but for the man whose health and life is under the care of one of these irregular practitioners, who beset in swarms the paths of the industrious classes with flattering but fallacious nostrums, all hope may be said to be extinct. Thousands of honest Englishmen are yearly slain by quackery and neglect, in consequence of the *bad position in which the regularly-educated men are placed* with regard to the working people. Yet, lamentable as must be the fate of these victims of disease, poverty, and imposture, there is another description of persons, whose sufferings appeal more strongly to our feelings: there are

many industrious men in the kingdom too poor to employ and to pay the *desired regular practitioner*—too spirited to apply to an overseer for the *parish doctor*, and who, rather than accept of any medical aid which they cannot purchase, suffer nature to take its course, and perish prematurely of diseases which might in many cases have been cured."

This appears to me the kind of reasoning that will find its way to the understandings of the governors of charities, and ultimately to the legislators of the country. Every medical man can illustrate the danger of quackery in his own experience, and the other argument may be freely illustrated by a reference to the Reports of the Poor Laws. It was those published in 1817 that convinced me my classification of labourers, which the public at present by no means appreciate, must some time come into notice, and which valuable Reports are continued in 1818, 1822, and 1833, more particularly the volume of "Extracts from the Information received by his Majesty's Commissioners as to the Administration and Operation of the Poor Laws."

Valuable and admirable as these Reports are, they are not equal in value to the Second Report of the Southam Dispensary, or the Second Report of the Coventry *Benevolent Dispensary. In that report, the road is marked out—the first step is taken, of redeeming upwards of two thousand five hundred beings from pauperism. It is in the power of the profession to follow that example, and aid the country generally more than all the acts of parliaments that the wisest government can pass.

It might be our duty to endure the evil of admitting improper persons to a dispensary—till a cure for the evil was discovered; but whoever reads attentively the Coventry Report will discover that there is no longer occasion to have our patience and humility imposed upon.

By those documents, along with the Rules of a Self-supporting Dispensary, it will be seen how to abate the great evil of which the Sheffield practitioners complain,—the recommending and admitting improper persons to their advice

* It is a pity that in the futile hope of conciliating the prejudices of some of the parties against the title *Self-supporting*, the governors consented to forego that name, and call it a *Benevolent Dispensary*. whilst, in fact, it is more self-supporting than almost any other.

in dispensary practice; for instance, a footman or butler taking wages of 50*l.* or 60*l.* per annum. Domestic servants are generally improper objects of charity: a servant-maid taking 8*l.* wages is better off than two-thirds of the population in the kingdom. See her approach the hospital with an out-patient's ticket, clothed and fed well: follow her, when married, to beg a ticket at a lying-in charity, and in a short time you may find her in the workhouse-yard, waiting for collection. The poor woman is not to blame; you may feed pigeons till they die of want.

Make her, and ten thousand like her, as soon as they earn wages, pay a penny, a half-penny, a pin's head, a something, if it be but to exhibit a token of self-dependence: if she or he is too poor in spirit, and will not pay this small tribute to freedom, class them at once with those who are poor in means and cannot pay. Let them come to the dispensary with a workhouse ticket, or they may still go to the parish doctor. Children of improvidence or misfortune, as it may happen in the portal of their ancient inheritance, parish pay, parish physie, and the parish workhouse, are still open to them, and must continue to be, till the working classes perceive *the bane the poor laws are to them* and their offspring. In every town a medical commission of three might be established, and make out a list of such persons who were proper to be relieved as patients at the dispensary; and I sincerely hope, for the sake of the working people themselves, as well as the medical practitioners, that what has been done at Coventry, Burton on Trent, and other places, will be copied at Sheffield and every other town and village in the king's dominion, commanding the service of a medical man. Let us no longer consent to be the slaves of a system that macadamizes the way to the workhouse, but be allowed the right of rejecting all persons whom we deem improper objects of charity.

I have the honour to remain

Your humble servant,

H. L. SMITH.

Southam, August 30, 1833.

PROTEST
AGAINST THE INDISCRIMINATE

RELIEF OF APPLICANTS AT
DISPENSARIES.

At a public meeting of the members of the medical profession of Sheffield, held at the Savings' Bank, on Wednesday evening the 31st July, Corden Thompson, M.D. in the chair, it was

Resolved,—That the following Memorial should be presented to the Governors of the Public Dispensary, at the special meeting to be held on Monday next.

To the Governors of the Sheffield Public Dispensary.

Gentlemen,—Viewing the great and continued abuses of the objects and intentions of a medical charity, which have existed in your institution, and which have for some time past been matter of notoriety, especially among the members of the profession; at a full and general meeting of the latter, held on the 22d instant, it was unanimously agreed to address you on the subject.

When your memorialists consider the large number of persons, compared with the population, who are receiving advice and medicine gratuitously, whether from the numerous benevolent societies, the various excellent parochial establishments, or the more strictly medical charities of the town and neighbourhood, they cannot resist the conclusion, *that gratuitous medical relief is already too extensively afforded*; and that here, as in all similar cases, the very facilities of obtaining such relief multiply the applicants for it beyond all reasonable bounds.

When, further, your memorialists reflect on the accumulated instances in which it has been undeniably ascertained that the circumstances of persons obtaining relief at your institution *have been such as to render them altogether improper objects of charity*, not only are they strengthened in the preceding conclusion, but they feel, and they wish to express that feeling in the most decided manner, *that they are suffering a serious injury at your hands.*

They are aware, gentlemen, that *your own medical officers*, with commendable

zeal, *have already represented to you this fact*; and in further corroboration thereof, you have now the united testimony of the profession.

It is not for your memorialists to dictate corrective measures, but they cannot refrain from expressing their opinion, the truth of which they think must be obvious to every capacity, that no effectual remedy against the abuses complained of will be found, *unless governors shall carefully examine into the circumstance of the patients whom they recommend*. The prevalent system of indiscriminate and unlimited recommendation, opens a door, of the very widest description, for the entrance of abuses.

Whilst the chief labour and toil, the anxiety and the responsibility, attached to our institution, devolve upon its medical officers, *whose services are gratuitous*, it were surely a matter of personal honour, to say nothing of right, that each governor should, on his part, exert himself to guard against any misappropriation of its benefits; to take care, in short, that the practitioner, whilst freely carrying the aims of benevolence into effect, is not himself defrauded of his just dues.

Charity, gentlemen, you are aware, like every other virtue, demands exertion on the part of those who practise it; and in the opinion of your memorialists, the mere annual subscription of a guinea, is far from constituting a benevolent or praiseworthy act, whilst at the same time the subscriber neglects to insure, so far as his knowledge and ability extend, the appropriation of that sum to the succour of really indigent persons. The individual trouble this might impose would be trifling; nor can the right of recommendation be said to be honestly and conscientiously exercised by such as shrink from that trouble.

Justice, it should be remembered, precedes generosity, and your memorialists cannot insist too strongly on this point, the disregard of which mars the purport of your institution, and at the same time *injures the intelligent and industrious practitioner*, without whose exertions its very existence ceases.

There is one class of patients, in particular, commonly relieved at your dispensary, that cannot in any way, your memorialists consider, be deemed proper objects of charity, so long as they retain their situation—namely, *domestic servants*.

And again, your memorialists are decidedly of opinion, *that the general employment of women in midwifery cases is strongly to be condemned*, since it does not afford to the patient the protection from danger, nor the skill and knowledge, essentially requisite at so critical a period as that of parturition. It is impossible to arrive at a correct conclusion on this subject by inspecting tables of deaths and recoveries from child-birth. The evils resulting from the practice alluded to are ulterior and consecutive. Lingerings, painful, and often fatal disorders, are the consequence of this practice,—a fact of which your memorialists have had too frequent and too sorrowful experience.

But independently of these serious considerations, your memorialists are unanimously of opinion, that an establishment of this nature connected with the dispensary is *altogether uncalled for*, since most ample provision for attendance in necessitous cases of midwifery *already exists at the poor house*. There, too, the plan which is acted upon prevents the possibility of improper objects being relieved.

Finally, gentlemen, it cannot surely be needful for your memorialists to advert to the notorious improvidence of the lower orders, *nor to the striking augmentation of that improvidence, which has universally been observed to follow the lavish extension of gratuitous relief*. Not only by this means are the good intentions of the charitable frustrated, but an increasing evil is inflicted on society, and that evil is transmitted to posterity.

Your memorialists have almost daily opportunity of witnessing the truth of these observations; of remarking how that which ought to be laid up against the accidents of life, is wasted in riotous and luxurious living; how evil habits are thus acquired, and the future is regarded with recklessness or indifference, because it is considered as already sufficiently cared for by others. And truly, gentlemen, unless some efficient measures be adopted to repress the growing abuse of your charity, the swelling numbers exhibited in each annual report, so far from yielding a means of estimating the amount of good effected, will rather tend to demonstrate the extent to which the evil has been carried.

Had not this evil already assumed an important magnitude, your memorialists would not have felt justified in thus

publicly addressing you. They were persuaded, however, that such a measure was imperative on them, not only in justice to themselves, but also in compliance with their duty to the public, who will thus be better enabled to judge of the extent to which your charity is entitled to support. And whilst your memorialists thus firmly, yet respectfully, express their sentiments, these, they doubt not, will receive from you all the consideration and attention which their importance demands.

MEDICAL GAZETTE.

Saturday, September 21, 1833.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dieendi periculum non recuso."

CICERO.

STATE OF THE METROPOLIS WITH REGARD TO CHOLERA.

WE have received a communication from one of the Foreign Consulates, informing us that the orders of their Government were peremptory, that they should be guided exclusively by what appeared in this journal on the subject of cholera, and that clean bills of health were not to be granted until we stated the disease to have subsided, whatever announcement might be made elsewhere. The same fact has formed the subject of

a letter addressed to us by a mercantile house in the city; with the addition that some of the Foreign Consuls will not grant clean bills so long as we mention the occurrence of any deaths from cholera, even though unaccompanied by any comment.

From this it would appear that our Government authorities have not escaped without some suspicion of their absolute good faith; and, indeed, it is consistent with our knowledge, that agents of the French and Spanish, and we believe also of the Russian and Swedish governments, had reported the re-appearance of the epidemic before it was openly avowed to exist. In making this remark, however, we do not mean to blame those employed by our own Government, because, while the benefit resulting from publicity is doubtful, the evil which results to commerce is great and immediate. But as society is constituted in this country, it is impossible for any exertion of authority, whether positive or negative, to conceal the presence of any prevalent malady; and therefore, when such exists, the announcement would come with a better grace from the fountain-head than from a collateral source, such as public rumour, or reports made in this or any other periodical. We allude particularly to the question now, because the same state of matters will in all human probability recur next season, and the line of conduct to be then pursued ought to be maturely weighed beforehand. We fear that the seeds of the disease lurk in every country in Europe, and will from time to time shew themselves under certain circumstances calculated to favour them, but of which circumstances little is yet known, except that they seem to be generally connected with a warm state of atmosphere. Cholera came to us from a hot climate, and in our colder regions seems to be favoured

by, if not absolutely to require, an analogous elevation of temperature. We therefore entirely concur in the sentiments of the Lords of the Privy Council, that they "wish it to be clearly understood, that they consider the disease may now be looked upon as domesticated in the greater part of Europe, in the same manner as the small-pox, and may therefore be expected to re-appear occasionally." If this be really the case, as we believe it is, then would it be of great importance that proper representations should be made to the foreign governments most concerned in our trade, that they may cease to strive against an enemy which has already shown itself too subtle to be opposed by sanitary enactments, and which, in fact, does not now require either ships or merchandize to convey it; for we hold that it has made its lodgment in every country in Europe, and though it may at the moment be dormant, is nevertheless ready to be developed when circumstances prove favourable.

As to the present state of the metropolis with regard to cholera—the disease has unquestionably greatly diminished during the last fortnight. Last year it became formidable in July; had attained its greatest severity by the end of August; and from that time declined. The same has been the case this season—with this favourable difference, that the numbers upon the whole have been smaller, and the decline has taken place rather earlier. With respect to the comparative degrees of prevalence during last year as compared to this, we believe that they will be found decidedly in favour of the present season. According to the Bills of Mortality, Aug. 14, 1832, the deaths from cholera amounted to 103; Aug. 13, 1833, to 186;—Aug. 21, 1832, they amounted to 116; Aug. 20, 1833, to 178;—Aug. 28, 1832, to 274; Aug. 27, 1833, to 125;—Sept. 4, 1832, to 157; Sept. 3, 1833,

to 69;—Sept. 11, 1832, to 257; Sept. 10, 1833, to 52;—Sept. 18, 1832, 154; Sept. 17, 1833, 29(?) *

Though as we have said the decline took place rather earlier than last season, yet it was then scarcely less rapid, the deaths by the Bills of Mortality having fallen, between Sept. 18 and Sept. 25, from 154 to 39!

Now with regard to the authority of the Bills of Mortality, they cannot be looked upon as absolutely accurate, but they certainly furnish us with an approximation to the truth as to the districts to which they refer, and perhaps, if we double the number of deaths from cholera reported in the "Bills," and assume this as the total number which has occurred in the metropolis, we shall not be far wide of the mark. According to the least favourable view of matters, cholera may with justice be said no longer to exist in London as an epidemic. The few cases that now occur are sporadic—do not spread—and in all human probability will soon disappear for the present. In our humble judgment, therefore, *there is nothing to warrant the withholding of clean bills of health from vessels proceeding from the port of London.*

ALDERSGATE DISPENSARY.

THE unhappy Secretary to this institution continues to figure in all the journals and newspapers, his name being appended to two daily begging advertisements—one for physicians and another for surgeons. But as yet, notwithstanding the easy terms offered, namely, that they shall have passed their examinations—*or shall be qualified to*

* The number in the Bills of Mortality for Sept. 17th is 101, but this includes 80 cases which have occurred *in five weeks* at Clerkenwell, and which were not previously reported. Dividing the 80 by 5 would give 16 per week; but as the disease has diminished so much during the last fortnight, we think that in taking as the present number one half of what it was when at the maximum, we are probably rather above than below the truth. — ED. GAZ.

have done so,—no candidate has appeared. Six vacancies, and none to fill them! why the Committee had better send about the common erier: surely there be some in London, amid the mass of eager aspirants in our profession, who would be persuaded to accept the offices, if not gratuitously, at least—for a consideration. Mr. Dalrymple, it is is true, offered himself, but immediately retracted on finding how matters stood: he did well, and did so just in time. He and Dr. Yates, of Wilton Crescent, attend at the Dispensary *pro tempore*: this is particularly good-natured on their parts, and indeed rather more than was necessary, as the late medical officers announced their intention of receiving the patients at their own houses till their successors were appointed. It will be disgraceful if physicians or surgeons be found to accept the appointments after what has passed, and the tradesmen, who compose the mass of governors of the Dispensary, thus be enabled to offer an insult to the whole medical profession. We therefore trust we shall see them compelled both to annul the motion which puts up the offices to sale, and to reinstate those who lately discharged the duties so faithfully as to receive an unanimous vote of thanks, couched in the strongest terms, from the very men, who, at the same moment, by passing a law derogatory to their respectability, forced them to retire.

A requisition, which originated with some of the independent Governors, is in course of signature, calling upon the Committee to take immediate steps to adjust the difference between them and the medical gentlemen.

MR. CROSSE, OF NORWICH.

This gentleman, who has taken great pains in communicating to his pupils the results of his own acute observation and extensive experience in the form of clinical lectures, has lately

received a gratifying mark of the value which his junior friends attach to his instructions. A few days ago they made him a present of a handsome piece of plate, which had been prepared unknown to him, and which bore the inscription—"Presented to J. G. CROSSE, Esq. by the PUPILS who have attended his Clinical Lectures at the Norfolk and Norwich Hospital, Sept. 17, 1833."

DR. GORDON SMITH.

WE regret to announce the death of Dr. Gordon Smith, lately Professor of Medical Jurisprudence at the Gower-street School. The place and circumstances of his death are of too painful a nature to be dwelt upon, and we therefore would rather advert to an earlier period of his career, when his faculties, being yet unimpaired by disease, he produced one or two works on Forensic Medicine, which contain a good deal of useful matter, though put together in rather a desultory and curious fashion. Of his later productions, which have appeared in some of our contemporaries, we shall only say, that as they bore internal evidence of the distressing circumstances under which they were penned, they ought in common feeling to have been suppressed.

ACADEMY OF MEDICINE, PARIS.

Tuesday, September 10, 1833.

M. BRESCHET IN THE CHAIR.

Remarkable Case of Extra-Uterine Pregnancy.

M. JULES CLOQUET read an account of a mummified fœtus, found in the dead body of a woman aged 78: it had been contained in a cyst in the left iliac fossa, adherent to the peritoneum, but perfectly detached from the uterus and fallopian tubes; it was a fœtus of three months, ossified; it was mutilated in the legs by the rough handling of the toll-keepers between Gènes and Paris.

M. Breschet looked upon this as an interesting case, for he did not know of any other well-authenticated instance of extra-uterine peritoneal pregnancy.

M. J. Cloquet observed, that though this sort of pregnancy had not been demonstrated as occurring in the human

species, it was common among animals: fifteen years ago he gave the faculty an account of a female cat, which had at her umbilicus two tumors, the size of large chesnuts, receiving their vessels from the peritoneum and adhering to the parietes of the abdomen. These tumors contained fœtuses quite independent of the uterus.

M. Velpeau thought that the fact of the existence of abdominal pregnancy was now abundantly proved; particularly by two cases lately published—one of them by M. Gaide, in the Archives, in which the whole uterine apparatus, tubes, ovaries, and all, were sound.

M. Capuron recollected a case which he had observed with M. Lisfranc, and an account of which he had communicated to the Academy: it was that of a lady who was supposed to labour under retroversion of the uterus. There was a tumor in the abdomen the size of the two fists, situated across, but quite distinct from, the sexual organs: a rounded opening gave issue to a fœtus into the rectum.

M. Velpeau reminded the Academy of the preparation in the possession of M. Esquirol, and an account of which was published, by M. Métivié, two or three years ago.

M. Esquirol said it belonged to a woman about 68 years of age, and the cyst that contained the fœtus was quite independent of the internal genital organs.

M. Moreau cited two similar cases; and

M. J. Cloquet added, that in the present instance the mummified fœtus was enveloped in a membrane, a centimetre in thickness, and that the mother had always enjoyed good health, and had borne three children.

GLASGOW ROYAL INFIRMARY.

[THE following cases we select from the *Clinical Reports* of Dr. MACFARLANE—a work containing much useful practical matter.]

ON PROLAPSUS OF THE ANUS.

This troublesome complaint, when it occurs in elderly people, may resist all the ordinary local remedies, and be curable only by a surgical operation. It is with the view of directing attention to the utility of the treatment recommended by the late Mr. Hey, of Leeds, in continued and

obstinate forms of the disease, that I shall shortly narrate the three following cases:—

CASE I.—*Prolapsus Ani, cured by Mr. Hey's Operation.*

A. M.D. æt. 58, admitted 15th May, 1826. Had been a patient in one of the medical wards for several weeks on account of diarrhœa, which was accompanied by tenesmus and prolapsus ani, with bloody and mucous evacuations. The bowel complaint was better; but the slightest straining, on attempting to empty the bladder or rectum, caused an immediate prolapsus. This also occurred when he got into an erect position, the tumor which formed appearing to be composed of two different parts. Close to the verge of the anus, there was observed a broad liver-coloured fold of the mucous membrane, which had an irregular surface, apparently produced by a varicose enlargement of the hemorrhoidal veins: this surrounded the larger and central tumor, which was evidently formed by a protrusion of the gut itself. A good deal of pain and hæmorrhage followed the descent of these parts, but they were readily returned when he was recumbent.

The total inefficacy of every mode of treatment which Dr. Brown, one of the physicians to the infirmary, had judiciously employed, and the existence of great relaxation of the integuments around the anus, led me to try Mr. Hey's operation. The whole loose integument was removed with a pair of curved scissors, along with a portion of its subjacent cellular texture, but without including any of the tuberculated fold of mucous membrane, which escaped from within the sphincter. A firm compress and T bandage were applied; he was confined in a recumbent position; proper attention was paid to his bowels; and although a prolapsus took place for several days on his going to stool, yet a cure was accomplished, and he left the house on the 16th of June.

CASE II.—*Prolapsus Ani, cured by Mr. Hey's Operation—Troublesome Hæmorrhage.*

E. W. about 50 years of age, had been affected with a prolapsus ani for nine months, and had tried a variety of treatment before he applied for my advice, in the waiting-room of the infirmary, on the 24th July, 1826. He had a sallow, unhealthy appearance; and the protruded parts, which escaped when he was standing, as well as when he went to stool, were large, thickened, livid, painful, and bled on the slightest touch. The loose integuments around the anus were removed by the curved scissors, along with

an irritable and slightly ulcerated portion of the mucous membrane, which was projected from within the sphincter. The hæmorrhage was rather profuse, but appeared to be arrested by the application of a cold compress, and firm pressure; it, however, returned in three hours: the patient became faintish and cold; he had an urgent desire to go to stool; and on removing the bandage and compress, he voided nearly a pound of coagulated blood. By using the dilator, a small bleeding vessel was secured within the sphincter, and both ends of the ligature cut off close to the knot. In a fortnight the prolapsus was effectually cured, and the patient speedily regained his former state of health.

The following case was cured by operation, after resisting every variety of treatment for about two years:—

CASE III.—*Prolapsus Ani—Operation—Cure.*

W. A. aged 54, became a district patient in the beginning of February 1829, on account of the above troublesome disease. The gut descended for more than two inches on every attempt to evacuate the bowels, accompanied by considerable pain and tenesmus. When he remained for a few minutes in an erect position, the same displacement took place slowly, although no propulsive efforts were employed; this, however, he could prevent by pressure on the anus. There was first projected from the anus, a circular fold of the mucous membrane of the rectum, at its verge of a livid colour and tuberculated appearance, soon followed by the complete descent of the bowel, and hæmorrhage from innumerable points. He generally succeeded in replacing the part by assuming the recumbent posture, and maintaining gentle, but continued pressure, for a few minutes. At an earlier period, however, the protrusion often continued for hours before it could be returned. His general health was greatly impaired, and he was unable to follow his employment, from the continued irritation and almost daily attacks of hæmorrhage.

On examining the anus after the gut was replaced, the surrounding integuments were found extremely relaxed. There existed such an unnatural looseness in the attachment of the skin around the anus to its corresponding cellular membrane, that it could be easily drawn out with the fingers, in the form of one or more large flaps. Having succeeded in two similar cases, which came under my care in the Royal Infirmary, during the summer of 1826, in completely curing the disease, by cutting off the loose integuments, as recommended by the late Mr. Hey, I determined to try it in this case. The skin was

drawn as far out as possible into broad flaps, and cut off with the scissors in a circular direction until all the superfluous integument was removed, including a portion of the livid and tuberculated fold of mucous membrane which was projected from within the sphincter. The pain was trifling, and only a few drops of blood were lost. A soft compress and T bandage were applied, and he was strictly confined to bed. For a few days, a partial procidentia took place on every attempt to go to stool. He had a good deal of pain and inflammation around the anus, with complete retention of urine, which required the frequent introduction of the catheter. In ten days after the operation, he was able to walk about, and void his stools, without any return of the disease, and in three weeks he was perfectly cured. Pressure was continued to the part for some time longer, occasional doses of castor oil were prescribed, and he was enjoined to avoid straining at stool.

There will generally be found, in obstinate and long-continued forms of this disease, a great relaxation in the connexion of the rectum at its lower part, with the surrounding textures. This circumstance, although it may not be the original cause, is sufficient, in many cases, to account for the continuance of the displacement in chronic and inveterate cases, although I believe it is generally accompanied by a diminished power of the sphincter. If the rectum, in consequence of being much irritated, as in various bowel complaints, ultimately becomes relaxed, the tenesmus, which is an invariable attendant, may so overcome the sphincter as to give rise to a procidentia. But when, as in the case now detailed, the erect position is sufficient to cause a descent of the gut, we have grounds for believing, that besides the relaxed state of the rectum, there exists a want of power in the sphincter muscle, which part, along with the levator ani, is mainly instrumental in maintaining the rectum in its natural situation. In the cases detailed by Mr. Hey, there existed, in combination with relaxation of the integuments, one or more livid tubercles at the verge of the anus, which were also removed. He expected from this operation, that inflammation of the surrounding cellular texture would be excited, the attachments of the rectum consolidated, and the power of sphincter improved. In a majority of cases the disease will be found to yield (although the cure is often tedious and protracted) to the local applications and internal remedies usually employed. Should it continue, however, as sometimes happens after the exciting cause has been removed, we will occasionally find that the loose state of the skin around the anus, and the relaxed attachments of the rectum

at its termination, become the primary causes of the continuance of the disease. It is, I conceive, in such circumstances that this simple operation may be beneficially adopted.

SPONTANEOUS AMPUTATION OF THE LEG.

M. DE LACOUX lately related to the Academy of Medicine a curious fact which came under his observation during the war with Russia. A Polish peasant having been bitten in the leg by a viper, put on a ligature in the manner which is traditionally usual among his countrymen. In four or five days the limb became sphacelated and detached: there was some little hæmorrhage, but it was easily stopped. The ligature consisted of a common cord, wrapped up in a handkerchief; and the place, where it was applied, was about four inches below the knee-pan. Almost the whole of the fibula was uncovered; the tibia not quite so much so; and the limb, previous to its separation, had become dried up and withered to about two-thirds of its natural size. — *Gazette des Hôpitaux*.

EFFECTS OF THE STING OF THE TARANTULA.

M. RINZI, a Neapolitan physician, lately read a memoir before the Académie de Médecine, on the subject of *Tarentisme*. The tarantula—the insect which gives rise to this affection—is of variable bulk; it is sometimes found as large as a beetle. Its sting produces at first a little inflammation, like that from the sting of a bee; the patient presently becomes gloomy and morose; his chest expands with difficulty; he has giddiness and irregular pulse; he falls into a state of moping, which can scarcely be dispelled. Music is generally employed by the people for the purpose; and the sounds of a violin or a bagpipe are deemed most efficacious for curing the disorder: “will he, nill he,” the patient sets to dance, he perspires, and never ceases till he falls asleep. This sleep cures him. The dance in question is the true *tarentella*. Ammonia, treacle, the saline waters in the environs of a neighbouring convent, fumigations, and citric acid in drinks, are also used; but dancing is the sure remedy for restoring the troubled innervation. Two or three cases were related by M. Rinzi. The memoir was referred to a commission, and the report by M. Virey has been not unfavourable; but instead of awarding their thanks to the author, it was agreed that M. Rinzi’s paper should be simply deposited in the archives. — *Journal Hebdomadaire*.

Except the 12th, 13th, and 15th, generally cloudy, with frequent rain.
Rain fallen, .575 of an inch.

CHARLES HENRY ADAMS.

NOTICES.

Several papers on the treatment of Cholera have been sent to us, particularly a very voluminous and elaborate one from Walsall. We have already said that we cannot find room for communications on this subject, unless they be very concise, and contain something really novel and useful.

We shall be glad to receive the *practical* letter offered by Mr. Smith.

Mr. Kimbaird’s offer is very kind: we should be glad to see the MSS. of which he speaks.

The second letter on Medical Nomenclature is not possessed of sufficient interest for our pages.

LECTURES
ON THE
THEORY AND PRACTICE OF
MEDICINE;

Delivered at the London University,

BY DR. ELLIOTSON.

LECTURE 116, and Last.

Gout continued.

Peculiarity of the pain.—The pain in gout is not only very severe, but of a very peculiar kind, so that Sydenham, in writing of his own sufferings, compares it to the gnawing of a dog; and patients who have suffered from it extremely, say they can distinguish between the pain of gout and that of rheumatism.

May occur in the most temperate persons.—In speaking of the predisposing causes of the disease, I mentioned that for the most part males suffer from it more than females; and that where it does occur in the latter, they are very robust. The males who experience it are chiefly those who are thick, stout, and of a sanguineous temperament; but occasionally you will see it in persons who are extremely thin, spare, and emaciated. The disease, although connected in a great number of cases with a certain development or form of body, yet certainly does arise in many instances independent of any external appearances whatever. Sometimes very delicate women are subject to it, persons whom you would imagine the least likely to suffer from it. In those cases where the external appearances are not such as would lead you to suppose that the patient would have it, there is usually a strong hereditary predisposition; but where this predisposition exists, you will

have it whether it is hereditary or not. You will meet with cases, not only where the external appearances are such as would lead you to suppose that the person would suffer the disease, but it will occur in the most temperate individuals—in persons whose habits are such, and have been such, as to make it very unlikely that they would have an attack of gout. The disposition to the disease may be exceedingly strong, and persons may become the victims of it independent of the external appearance of the body, and independent of any of those excesses which so frequently produce it.

Increased frequency of the paroxysms, and vice versa.—I stated with regard to the progress of the disease, that it generally begins in one great toe; that on the second attack it perhaps occurs in both, and so it spreads to the other joints, till at last, after several paroxysms, many joints will be affected. And not only does the disease become more extensive, but it also becomes more frequent, so that persons at first, perhaps, have a paroxysm every year or two, and then every year; then two or three paroxysms in a year, and at last they are scarcely ever without it; they have it on the least exciting cause. I should have mentioned also, that some persons never have above two or three fits in the course of their life. I know an instance of an individual who, when about thirty-five years of age, had an attack of regular gout, and, although he is now upwards of seventy, he has never had an attack since, without having done any thing particularly to avoid it. These are exceptions to general rules.

Gout formerly longed for.—I mentioned that many symptoms will cease when an attack of gout appears, so that it is a very common thing for persons who have suffered in various ways to suffer no longer after they have had a fit of the gout. This fact made so great an impression on the public at one time, that gout was longed

after as a great blessing; and people with all sorts of complaints would eat and drink, take a large quantity of wine, and do all they could to have a fit of the gout. As it is a disease which attacks the rich more than the poor, it was altogether a fashionable complaint; it was thought a creditable disease, and at one time every body longed for it, or declared that they had had it. You will find this whim strongly argued against in Dr. Heberden's Commentaries, which it will be worth your while to read, not only on account of the elegant Latin, but the excellent description which he gives of the disease, although for the most part he adopted inert and poor treatment.

Influence of ardent spirits.—The disease, I mentioned, is particularly favoured by an indulgence in wine. All fermented liquors do not appear to give the same tendency to it; and as to spirits, I am inclined to believe that, so far from disposing persons to the disease, they have a tendency to prevent it; at least, I hardly know an instance of a person who has committed a great excess in spirits labouring under the disease, although wine-drinkers have it every day. It is a very rare complaint among the poor: now and then you will see it among them, because there is a peculiar predisposition to it in some persons, and sometimes it is hereditary, and will occur in spite of the absence of all the ordinary causes; but, for the most part, you will not meet with it in the lower walks of life. I have seen persons who, from their make of body, from the occurrence of the disease in their progenitors—many members of the family having had it—were the most likely persons in the world to experience it, but who, from indulging in spirits to excess, and to a disgraceful excess—for excess of that kind is always disgraceful—have not suffered from it, although beforehand one would have said that they were most likely to have it by the time they were forty or fifty.

Paroxysms induced by slight causes.—When a person is liable to gout, a paroxysm may be induced by the very slightest cause. If he indulge in eating and drinking too much on any particular occasion, a fit of the gout is very likely to be the consequence; it will occasionally ensue from mental anxiety. An exposure to cold, which in another individual would induce an inflammatory complaint, will in those predisposed to gout produce a paroxysm. Even accidents, a sprain of a joint, will become local causes, and the patient will have an attack of gout in that particular part.

Affection of internal organs.—When persons have the disease for a length of time,

it is very common for internal organs to become seriously diseased. It is very usual to see persons who have been the victims of gout become asthmatic, have disease of the kidneys, have organic diseases of the stomach and intestines, have chronic bronchitis; very frequently disease of the heart supervenes, and disease of the head occurs, so that they die apoplectic. The gout is not confined at last to the extremities, neither are the internal symptoms merely functional, but the organs in the three great cavities of the body become diseased.

Prognosis.—As to the prognosis, that must depend on the degree of the original disposition on the part of the patient to the disease, and it must depend, of course, in a great measure also, upon the resolution which he has to follow up our advice. A great number of persons who have the gout are very disobedient in this particular.

Treatment.—With respect to the cure of the gout, in general it is necessary that the patient should be very abstemious—live as low as he can to be in good health, and take as much exercise as he can bear, taking care that his health is not impaired by its violence. It is impossible to lay down any specific rule; and to say that a man disposed to gout should not drink wine, should not drink beer, should not eat meat, would be wrong. There are some gouty patients who would be better if they cut off fermented liquors, others would be better if they went farther, and ate no meat, but confined themselves to vegetable diet and milk. There are other cases again where this would be absurd, the patient could not live without meat; and there are other cases where it is necessary to allow a certain quantity of wine. The rule should be, to let patients live as low as they can to be in good health; and that must vary in different individuals. The stomach of many persons labouring under gout is so weak, that they cannot digest their food without a certain allowance of wine; but, generally speaking, the diet I have recommended, and as much pleasant exercise as possible, without weakening the patient, is advisable. There should, however, no doubt be extreme temperance; the patient should not take more wine, or eat more meat, than is necessary. No doubt many persons will thus get rid of the gout altogether, with the most perfect ease; and no doubt others, who will not get rid of it (and these may be by far the larger number), will have it very much mitigated. It is necessary that they should be particular in their food; that if they eat any food they should take that which is the most digestible, such as fresh mutton, fresh beef, without any sauce or elaborate preparation on the part of the cook. They

should take simply Sherry or Madeira, not mixed wines; and above all they should not take acescent wines, not take Champagne; and perhaps they had better take brandy and water. Many persons from taking Rhenish wines, or Claret, or Champagne, have a fit of the gout directly. In general Sherry agrees best, and therefore you should recommend it, unless the person knows from his own experience that some other wine is better for his constitution, or a small quantity of brandy mixed with water. I am supposing that the stomach of the patient requires that such a plan should be adopted.

Friction is exceedingly useful where exercise cannot be adopted. It would be well for many persons who are lame in the feet, to be rubbed down once or twice a day like a horse; it would be very beneficial in a great number of cases, and they would find it to be a very great luxury.

In a regular fit of the gout, the best medicine that can be given is colchicum. You should exhibit the wine in half-drachm doses every six hours, mixed with some other purgative, because you want its action to be speedy. The sulphate of magnesia is a good combination; you may produce purging in twenty-four hours, or sooner, and when that takes place the patient is generally relieved at once. Any good active purgative will have a beneficial effect, but colchicum appears to be more efficacious than any other: unless it purges, however, it will seldom have any influence. Now and then the symptoms will all cease after two or three doses; but in the greater number of instances so desirable a result does not occur till purging takes place. It is better to quicken the purgative effect, in order to prevent it from griping, and the sulphate of magnesia will excite its action so much the sooner. Venesection in young persons may be advisable, but in general it is out of the question. Leeches applied to the part are frequently productive of very great alleviation, and it is a great comfort generally to apply an evaporating lotion, not cold, but tepid. A spirituous lotion applied tepid, so as not to produce a chilly effect, is generally serviceable. There can be no doubt frequently of the great use of colchicum, and of evaporating lotions; and when they are being employed, the diet should be scanty.

When the paroxysm is over (and it need never last long if you treat it in this way), friction of the parts is always found useful; rubbing them with a flesh-brush, or the hand, and some salt and water, and similar stimulants. Sometimes it is necessary to give wine, or mild tonics, to relieve the languor that is left, but it is by no means *always* necessary. Occasionally,

from the great severity of the pain, opiates may be required, but it is necessary to use the antiphlogistic measures that I mentioned. If all this be done, and the patient's life is continued, the disease becomes comparatively trifling; I say *comparatively*, because it is always painful, and therefore there is more or less suffering, but it is nothing like so painful as it would be if they wrapped up their limbs in flannel, took no colchicum, and in the intervals of the disease indulged in every absurd way they could.

It is dangerous to apply cold to the parts during an attack of gout; some have done it; and Harvey, who discovered the circulation of the blood, was accustomed when an attack came, to plunge his feet in a pail of cold water. I know persons that do this, but no medical man is justified in recommending it, for it has frequently happened that some disease has suddenly begun within; there has been apoplexy induced, or violent gastrodynia, or an affection of the heart, and the patient has died very shortly. If the patient chooses to do it on his own risk, he may, but he ought to be warned of the consequences by his medical man.

It is a disease which it is not easy to eradicate; but by the employment of colchicum the disease is rendered much less violent than it was a few years ago. Formerly colchicum was employed with great success, and then it was forgotten entirely till within a very few years ago. When I was a student, no one thought of exhibiting colchicum in any form; it was only spoken of as a thing once used, as an uncertain diuretic and a violent purgative, and it was thought it would be better if it were expunged from the *Materia Medica*.

I spoke of the wine of colchicum, but the powder and other preparations are very good. I have been in the habit of using the wine, and it has answered very well. Some give the powder in doses of five grains every four or six hours, and some give the acetum. In general it certainly does no good till it purges, though sometimes the opposite is the case.

RHEUMATISM.

The next disease of which I will speak is nearly allied to gout in many particulars, and is called *rheumatism*.

Etymology.—As gout is named from the idea of the dropping of morbid fluid, so rheumatism is named from a similar idea, from the Greek word *ρευματισμός*.

It is said that gout and rheumatism were not accurately distinguished from each other till the year 1642, both of them passing under the name of *arthritis*. Bellonius, who was a physician that suffered much

from rheumatism, is said to have been the first that made an accurate distinction.

Occurs in two forms.—Now rheumatism may occur in an active, or a dull passive form; and the two varieties require very opposite treatment.

Symptoms.—In the active form of rheumatism, that which is commonly called acute rheumatism, there is heat and pain, and in most instances a swelling of the joints. These are not the smaller joints, as is the case in gout, but the large ones, in general the wrists, the ankles, the elbows, the knees, the shoulders, and the hips. When these parts are affected with it there is pain, but nothing of that violent kind which occurs in gout, as if a dog were gnawing the joint. It is as violent as a patient could wish it to be, but by no means so horrid as gout. The parts are generally hot and red; and frequently, from the pain being situated in the theca of the tendons, I have seen red streaks running in the situation of the tendons. There is generally swelling and puffiness in some part. Usually there is feverishness, pyrexia, and a quick pulse; the pulse is not hard, but it is generally full and soft; the tongue is not foul and dry, but generally very white; and the urine is high-coloured, and deposits a lateritious sediment.

Diagnosis from Gout.—This disease does not begin, like gout, in the night particularly, but invades at any time; and it does not come on at any particular season of the year. It arises from an evident exciting cause, and therefore it may come on at any time. It does not confine itself to one joint particularly, but leaves one and goes to another; and it will attack two or three at the same time. There is a shifting about it; it migrates in the most singular manner. There is not only heat and an increased temperature, but heat generally makes the patient worse; there is usually too profuse sweating, and the sweats are often exceedingly sour to the smell. When the disease goes off, the parts do not desquamate and itch as they do after gout, but they merely cease to be hot, cease to swell, and cease to be inflamed.

The same symptoms accompany the chronic form.—Now this is the usual state of things when the disease begins suddenly as an acute disease; but you will find a similar state of things in the chronic form. When the disease has lasted a twelvemonth, you will find the parts still hot, still swollen, and of course still painful, and the pain is increased if heat be applied. You will find the same symptoms as in the acute affection, only they are less violent. In general, however, the sweating does not continue; after the disease has lasted a

few weeks this symptom ceases, and the patient perhaps forgets it. It is sometimes a little difficult to make an accurate diagnosis, at least it requires a little trouble; and it is well to ask about the sweating. If the disease have been acute rheumatism at first, you will find there has been sweating, at least it is unusual for a person not to sweat at the beginning of the disease.

Not confined to the joints.—Although the joints are the parts particularly affected, yet persons frequently have the disease in the back, and then it is called *lumbago*. Frequently it occurs in the back of the neck, and then the patient is said to have a *crick in the neck*. It may affect the face, and indeed it may effect almost every part of the body where there is fibrous membrane, aponeuroses, ligaments, tendons, or perhaps muscles.

Thoracic membranes frequently affected.—There is no danger whatever from this disease, excepting from one circumstance, which is, that the membranes within the chest are liable to be affected—that is to say, the pericardium and the pleura. They are sometimes attacked during the disease, but when the disease has suddenly ceased, or has gone off gradually, inflammation within sometimes takes place. This internal inflammation will occur at all periods, and under all possible circumstances, but it most frequently takes place about the time of puberty, and in young adults, so that in acute rheumatism you should never omit observing the state of the chest, just as in the case of an obstruction of the bowels it is right to ascertain whether there is a hernia or not. Now and then inflammation occurs within the head, and phrenitis is set up, but that is rare; whereas inflammation of the pleura and pericardium, particularly the latter, are very common.

Atonic Rheumatism—Acute and Chronic.—The active form of the disease, I mentioned, may be acute or chronic: the chronic form may have active symptoms, but very frequently it has not; the parts are not hotter than they ought to be, but on the contrary they are relieved by heat. This is sometimes the case in the acute form of the disease; that is to say, occasionally persons when they are first attacked with rheumatism have no heat—the pain is not aggravated by heat, but the parts are cold, and are better for heat. It is generally, however, in the chronic form of the disease that the parts fall into this state of atony.

Sometimes consists of violent pain only.—The disease sometimes appears to consist of little more than violent pain. You will sometimes hear people complain of pain apparently in the muscles, but it may be

situated in the aponeuroses over the muscles. There is simply pain on motion, which is not increased at all on pressure, and there is no swelling, and then it has been called *rheumatalgia*. I do not know the necessity for giving it this name. But although rheumatism generally affects the fibrous membranes, yet sometimes it affects apparently the muscular fibres, and sometimes it appears to affect the nerves or the covering of the nerves, so that it will distinctly run down the sciatic nerve, though it is most frequently seen in the nerves of the face. I mentioned, when speaking of *tic douloureux*, that sometimes, besides the genuine form of that disease, you have another affection, called *neuralgia*, which is easily cured. When rheumatism affects the nerves, it clearly exists in their course, and then it frequently assumes an intermittent form. This is particularly the case in the head.

Sometimes Intermittent.—Rheumatism is sometimes intermittent when it does not affect the nerves particularly, but when it affects aponeuroses, and this form of the disease most frequently attacks the head. In this case it usually affects one half of the organ, and the pain generally comes on in the evening about six o'clock, and continues very violently for a few hours. Occasionally, when it is intermittent in this way, the parts are hot, swollen, and throb, and the eyes water; but in other cases this is not felt, and the patient is all the better for wrapping up his head in his wife's flannel petticoat, or if the patient be a lady, she wraps it up in her own. This is done by the lower orders, and with very good effect.

Thickening of the affected parts.—Occasionally the parts, when long affected with the disease, become thickened: you will have considerable thickening of the joints, and the small joints of the fingers will throb from time to time, and the patient will become a cripple, in consequence of the joints being inflexible, just as in the case of gout.

Rheumatic Gout.—When rheumatism affects the smaller joints in the same way as gout, it is called by the common people *rheumatic gout*, not that it is a combination of the two, though it sometimes may be. But as gout affects the small and rheumatism the large joints, if rheumatism should affect the small joints, then it is usually termed "*rheumatic gout*." You may have the same appearances both from gout and rheumatism.

Exciting Cause.—There is, I believe, but one exciting cause of the disease, and that is the application of cold, or cold and wet, more especially if the patient be fatigued. I do not know that I ever saw a case in

my life that arose from any other circumstance.

Termination.—I mentioned before, when speaking of inflammation generally, that rheumatism does not terminate in suppuration, and if suppuration occur, it must arise from another inflammation being accidentally present, or excited by it. Neither does it terminate in mortification. There is effusion sometimes in the joints; a considerable secretion of synovia or of fluid in the bursæ, and sometimes in the tendons: but the parts may become rigid; you may have this effect of inflammation; and then sometimes mortification has been the consequence.

Occurs in Infants.—Rheumatism will occur in infants as well as in old people, and this is worth knowing. I have seen many cases of the disease in the youngest children—a circumstance very likely to be passed over; and I have seen disease of the heart in the youngest children, as a consequence of pericarditis excited by this disease.

Treatment.—As to the treatment of the affection, whether it is acute or chronic, it would be exactly the same. You have only to make two distinctions, to ascertain whether it is the inflammatory form of the disease—whether the parts are hotter than they should be—whether heat does harm; or whether the parts are cooler than they should be, and heat does good. In the one case, antiphlogistic measures will be required; and in the other, stimulants.

Sometimes, where the patient is plethoric, it is advisable to take away blood from the arm, and you will find it bled and cupped, but there is no danger whatever from that circumstance; for if you go on bleeding, you may find the blood bled and cupped till you have got nearly all the blood out of the body. But venesection is not always required; free local bleeding generally answers better; but there is no objection to general bleeding, if the strength will allow it; and if several large joints be affected, it will then be better than local bleeding.

With respect to the parts themselves, whether you apply leeches or cupping, or not, you will find it of great use to apply cold water or lotions as long as the temperature is higher than it ought to be, and it feels comfortable to the patient. There is no danger in applying cold under these limitations. If the patient should be timid, and yet long for cold evaporating lotions, as in the case of gout, they may be applied tepid; but I never saw injury arise from applying cold in rheumatism, where the parts were hotter than they should be, and the patient felt hot.

The two best internal medicines are

without doubt colchicum and mercury. Colchicum here, as in the case of gout, generally does no good till it purges, and when once it purges the patient thoroughly, the disease usually gives way. It should be given the same way as in gout, that is to say, with magnesia, that it may produce its effect as speedily as possible. As soon as it purges, it is right to desist, and also as soon as its effect ceases. If you give a dose of hydrocyanic acid with the colchicum, it sits better on the stomach: you may exhibit 1, 2, or 3 minims.

But you will every now and then find obstinate cases, which will not easily give way, although the greater part of them do, and then it is a pity to go on with the colchicum: you had better exhibit mercury, and get the mouth tender. If you do this, in the first instance, instead of giving colchicum, the success is about the same. Colchicum may gripe, and mercury may make the mouth sore, so that you may not be able to continue them, and you may then leave off the one, whichever it may be, and exhibit the other; or if you begin with one of them first, and find it does no good, then you may exhibit the other.

As soon as the inflammatory symptoms are gone down, and the patient has been properly evacuated, many give bark and quinine; and it is said that bark is a safe and good remedy in active inflammatory rheumatism, but you will not find in Haygarth's work any authority for such practice. You will find, in his book, accounts of the successful treatment of rheumatism by bark, but then it was not till he had evacuated the patient upwards and downwards, and employed the antiphlogistic plan. After that, it is said that it prevented the disease from recurring. I have not had occasion to use bark, for I have found the disease give way under the treatment I have mentioned.

It may be right to give narcotics, in order to produce ease, and a full dose of opium may be proper at night. There is no harm in it provided you adopt antiphlogistic measures, and provided you bleed as far as bleeding is indicated, and provided you purge the patient well, and apply cold.

Exactly the same treatment is proper in the chronic form of the disease, if there are inflammatory symptoms; but whether the disease be recent or chronic, if the parts are not in this condition, an opposite plan should be adopted, and it is right to stimulate the parts. In this case you will find friction an excellent remedy; and you will find the hot bath, particularly the vapour bath, very useful. If the patient find alleviation from warmth and stimulants of all kinds, or the parts are colder than they

should be, then this plan should be put in practice. The hot bath should be employed, not every other day, but every day, and sometimes twice a day in cases of extreme coldness and extreme pain. It is here that electricity is of use, and friction of all kinds, together with stimulating washes, stimulating liniments, and croton oil, which is a good stimulant externally, and does not purge when it is so employed. Tartar emetic and sometimes moxa have been employed, but only, of course, in very severe cases.

It is in this description of the complaint that you find acupuncture of great use. It is only in the fleshy parts that you can introduce the needle: I should never advise it to be put into tendons and joints, though I have seen such things done. In general, it is only in the fleshy parts, such as the deltoid, the biceps, the gastrocnemius, the rectus, or the gluteus muscles, that it is right to put them. The best mode is to roll them, in pressing them between your fingers, and they will soon pass to the desired length. You may insert them an inch and a half in depth, and if the bone is in the way, as in the case of the os femoris, there is no harm in the needle coming upon it, though there is no use in it; but they may go as far. The success of the operation does not depend on the number of needles, but the time they remain in. If it be comfortable to the patient, you may let them remain in a couple of hours; that is, as long as a patient can bear to be kept still. There is no pain worth notice when they are introduced, and when they are in, there is no pain at all. It should be done every day, and occasionally you will find relief as soon as they are taken out the first time, but in other instances not till they have been employed two or three times, or perhaps more than that. It is only where the parts are not hotter than they should be that acupuncture is of any use: I never saw it do good when heat increased the pain. Acupuncture is not an absurd remedy; it is a strong one; but I am quite satisfied it is a real remedy, if it be properly applied.

In the chronic form of rheumatism, you will find mercury of the same use as in an acute attack. Whether the parts are hotter than they should be or not, you will find obstinate cases give way to mercury when they will not yield to any other medicine. Nothing is more common than for persons who are the victims of chronic rheumatism, whether it be inflammatory or not, but who are suffering great pain, and more especially if the pain be worse at night, to receive no benefit whatever till they have a course of mercury; and as

soon as the mouth is sore, they will lose all the pain. Mercury appears equally useful in both kinds of rheumatism. You will find that one of the best internal stimulants in this sort of case is the ammoniated tincture of guaiacum. Guaiacum is a stimulating diaphoretic, and is very useful in this form of rheumatism, though it is of no service in the active form of the complaint. If you give the tincture from the spirits and ammonia you produce great warmth, and the patient remains warm for a longer or a shorter time. This is a medicine that may be given in various doses; some persons are made hot with 30 drops, but others will take a drachm, and I have seen some who have taken six drachms, three or four times a day. There is no rule for it; but you should begin with half a drachm, and as long as the patient is not warmed by it, and does not find it irritate him, you may increase it. You will sometimes find the warmth last one, two, or three hours, and from a proper course you will find great alleviation from it. Sometimes it purges—sometimes it irritates the skin, and produces the nettle-rash; but when internal stimulants are necessary in rheumatism, I think this is one of the best. In the chronic form of the complaint, it is often necessary to support the patient well—to give him wine, and nourish him exceedingly.

Arsenic has an excellent effect in this form of the disease, where the joints become cold. It frequently requires to be well persevered in, and you will find it borne by the stomach, just like colchicum, infinitely better if you give prussic acid a little before it, or at the same time. Arsenic is a medicine which is much disposed to irritate the stomach and bowels, to produce gastritis, and, short of that, it frequently produces nausea and vomiting; but that may generally be prevented by prussic acid. The moment you find heat in the stomach and bowels, and pain on pressure, it should be omitted. You should ascertain this point every day; and when it occurs, the medicine should not be resumed till these symptoms have gone off. Arsenic also produces soreness of the eyes, and redness of the throat, and when any of these symptoms arise, you must desist from exhibiting the medicine, and not resume it till they are gone off. As to the dose, there is no particular rule for it: it is best to begin with two or three minims, and as long as it is borne without doing the patient any harm, you may increase it. I have known cases where thirteen or fourteen minims were borne, but that is a large dose; in general, seven or eight minims are as much as can be given. I do not know that there is any danger in

the œdema induced by the medicine, but it shows that it acts on the body, and therefore it is better to desist. With regard to the gastritic affection, that would be dangerous if the arsenic were continued; but with a careful practitioner, no danger can arise from this remedy. In the chronic form of the disease, blisters, setons, and moxæ, may be of use, just as in any other chronic inflammation.

If the disease assume an intermittent form, you must treat it in some measure as intermittent fever, give a large dose of quinine or bark, either just before a paroxysm is expected, or afterwards, and smaller doses in the intervals; or you may employ arsenic. A large dose of a narcotic, given just when the paroxysm is about to begin, often acts like a charm when rheumatism affects the face. It is an excellent plan to give a dose of stramonium at the time the pain is coming on, and repeat it in two or three hours. A large dose is generally required, and therefore it is better to give a grain to an adult, and in two or three hours, if there be no alleviation of the pain and no affection of the head, then repeat it. Sometimes the pain will not cease till you have exhibited two or three doses; but I do not know above one or two cases in which this plan failed: it is certainly one of the best you can adopt. The ill effects of stramonium, I before mentioned, are dimness of sight, great thirst, and dryness of throat; but these are not at all dangerous symptoms. The most unpleasant symptom is an affection of the head, drowsiness, giddiness, or delirium. I have frequently seen these induced, and then go away after a few hours; but if there be any hazard, an emetic may be had recourse to; if, however, you increase the dose slowly, this effect need hardly ever occur.

CONCLUDING ADDRESS.

We have now arrived at what I intend to be the conclusion of the course. I have spoken of an immense number of diseases to which flesh is heir, and I have endeavoured to tell you all I myself know about them.

I of course must rejoice, as I am sure you do, that our labours are at an end; that is a natural feeling for both of us. I am sorry to part with you, because I have every reason to be delighted with the attention I have received during the course; yet as we are all anxious for a remission of laborious exertion, I congratulate you that the scene of my labours is at a close.

I have endeavoured to speak of all those diseases which usually come under the care of the medical practitioner. I have not di-

gressed in order to speak of other diseases, and to mention a number of other subjects, because I knew that I had so much on hand that the time would scarcely be sufficient to do justice to those which came particularly in my own province. It may be that there are some other diseases which I ought to have spoken of, but I do not think there are any which I have omitted that are not fully treated of in other courses: I allude to surgical diseases, and diseases of the female organs of generation, a few of which, although they may come under the treatment of the physician, yet they must be particularly spoken of by the professors of surgery and midwifery. I have taken advantage of that circumstance to pass over some affections, which I am in the habit of treating in private practice every day. I hope I have not wasted any time in displaying my knowledge on topics foreign to this course of lectures, because I had too many of my own to be desirous of saying any thing more than was strictly necessary in my particular department.

You are aware that all the instructions given can be no avail unless you see the facts, which are stated, verified. Unfortunately, in this institution, we have not the means of giving that instruction which is necessary; but I believe I may assure you, that before this time twelve-month, the most active means will be taken for affording clinical, medical, surgical, and obstetric instruction. I have advanced nothing marvellous in order to produce an effect, but I have been anxious simply to inculcate real truth, so far as I myself am aware that it is truth.

I do not know whether it is usual now, but it was when I was a student, to give advice at the end of a course as to your future conduct. I am not one of those who are disposed to give much advice, because I suppose every gentleman here knows what is right and what is wrong. I am sure the attempt to quote Scripture or preach a sermon to you would be quite out of place.

But there are two things which I am particularly anxious to impress upon you, and these are—that *in your profession you will never lose sight of its real delight*—that you will never become mere practitioners, going about to see your patients and ordering medicines just as a baker goes distributing loaves round a parish, but that you will consider it a source of true intellectual delight. There is hardly a case that occurs that may not afford you an intellectual exercise, and enable you to advance your own knowledge a little. Very few practitioners, I am sure, pass six months in the year without having an opportunity of advancing, not only their own knowledge, but adding to the general stock. If

you become mere, dull, routine practitioners, I shall indeed be extremely sorry. I trust you will always consider, that although you enter the profession for the purpose of gaining a livelihood, yet happily in our pursuits there is an infinitely greater delight than this—that we have the means of leading the lives of philosophers—of using our intellect and improving science, which cannot be said of a large number of occupations to which men are unfortunately destined.

The other point to which I wish to direct your attention is, *to avoid every thing that can bring the profession into disgrace*. We all witness medical squabbles, and I think nothing can be more contemptible than personal jealousies carried on so unfortunately as we often see them. When you are in practice, never give an opinion upon any case unless it is in your own hands. When a case is under the care of another individual, never should an opinion be given upon it, unless it be to corroborate what he has said, and establish him in the estimation of the patient. If you see a man treating a patient in a disgraceful manner that is another case; but even then it is much better to see the individual himself than to make any disturbance about it. When you are attending with another practitioner, nothing should be done to lower him in the opinion of the patient. It is right, if you can, always to express your coincidence of sentiment with a brother practitioner; and if you differ from him, you should not let the patient know it, but argue the point in private. Never say any thing to make a patient think you would have treated him better than your predecessor. If it so happen that a medical man should ill treat you, (and we must all expect to meet with that,) it is best to keep the matter quiet; because if you complain of being wronged, the world will only shake their heads and significantly say, “two of a trade—two of a trade,” and you will gain nothing by it. When your conscience satisfies you that you are the injured person, it is best to learn to pass things over, and avoid as much as possible any appearance of a medical squabble to the world.

I will not pretend to lamentation and grief at parting with you, because I shall have to part with some every year, and I must reserve my tears and lamentations for more serious occasions. I feel the greatest obligation to you for the kindness with which you have listened to me, and I owe you an apology for having frequently been late, but I assure you it was unavoidable. In fine, I can only say, that on any occasion on which I can be of use to you, it will afford me the greatest pleasure.

CLINICAL OBSERVATIONS

ON THE

LIGATURE OF ARTERIES

Between the Aneurismal Tumor and the Capillary Vessels.

By BARON DUPUYTREN.

From the "Leçons Orales," published periodically, under the Baron's inspection.

THE ligature of arteries, as we have seen, may be effected between the tumor and the heart,—and this is the method most commonly adopted; but there are circumstances in which it cannot be practised, in consequence of the aneurism being too near the centre of circulation. The disease then continues to advance, notwithstanding the debilitating means and refrigerant applications of the surgeon; and the surgeon has then no resource left but to apply the ligature between the tumor and the capillaries. The idea of this proceeding originated with Brasdor, but Deschamps was the first to practise it on the living body. He tied the femoral artery below the tumor, for an inguinal aneurism. The disease rapidly increased in size; and in order to prevent the bursting of the vessel, and death of the patient, he was obliged to open the sac and tie the artery above it. The patient died in eight hours after, having lost a large quantity of blood. The first operation, however, was very badly performed, as the profunda femoris and some muscular fibres were included in the ligature. This attempt then, and one equally unsuccessful made by Astley Cooper, had thrown discredit on the proceeding, when other trials, made with various success, again directed attention to it*.

It appears beyond a doubt, that the unfavourable results in these two cases depended on the circumstance of some important arterial branch being situated between the ligature and the aneurism. Accordingly, the general opinion at the present day is, that the chances of recovery are the greatest possible, when no vessel capable of keeping up the circulation is interposed between the ligature and the aneurism. This favourable result may also take place although some very small

branches arise near the aneurism, as the coagulum may gradually extend into them. On the other hand, the existence of branches of such size as to oppose the formation of a coagulum, render the operation nugatory; nay more,—it may be worse than useless, and hurry on the fatal progress of the disease, as may be readily conceived; the effort of the blood propelled by the heart being constantly to overcome the impediment, and the sac must of course participate in the effects of this propulsive force. This method of operating does not apply to aneurism arising from injuries, or which are recent, or diffused, or of the varicose species; but to those which are spontaneous, or to circumscribed traumatic aneurisms with firm sacs. The situation of the epigastric artery is an obstacle to the performance of this operation in the thigh; we must therefore begin by tying it, in order to secure success.

If we look to the favourable cases, we shall find that of five instances of ligature, where no arterial branch took its origin between the point of its application and the aneurismal sac, three were followed by complete recovery; while in the opposite cases the greater number of the aneurisms, and particularly those in the groin and the axilla, have not been arrested by this operation. In some others, particularly at the lower part of the neck, the progress of the disease has not only been arrested, but subdued for eight months, and even for two years.

The following case, though not followed by success, does not on that account less deserve attention, as the failure is not attributable to the nature of the operation, but to other extraneous causes.

Aneurism of the Subclavian Artery—Ligature of the Axillary—Death—Dissection.

[An exceedingly prolix account of the case is here given. As, however, we published the details in full at the time of its occurrence (see Medical Gazette, vol. iv. pp. 123 and 221), we shall content ourselves with recapitulating the chief points, that the observations of M. Dupuytren may be intelligible, referring to the above source for farther particulars.]

— Charlemagne, aged 40, a workman of robust constitution, four months before his admission into the Hôtel Dieu, experienced pain above the right shoulder after having made some violent exertion. In three days a pulsating tumor was visible, about the size of a nut, and situated just above the clavicle. Bleeding and cold applications were insufficient to arrest its progress, and he came to the hospital May 28, 1829. The tumor was now large and projecting, without discoloration, occupying the lower part of the neck, and having

* It is altogether impossible that M. Dupuytren should either be ignorant of Mr. Wardrop's operations, or that he should not, in fact, have made the above remarks in reference to them; and yet he has not the candour to mention his name. This unamiable spirit, we regret to say, is too observable in the productions of M. Dupuytren; he is ready enough to refer to Sir Astley Cooper by name, if he has any failure to mention; and the same remark even applies to his own countrymen, of whom he seems equally jealous.—TRANSLATOR.

the clavicle for its basis. M. Dupuytren saw the necessity of performing an operation, to prevent the otherwise inevitable result, as the tumor, if left to itself, must necessarily burst. The impossibility of tying the vessel between the aneurism and the heart, left no choice but to apply a ligature to the axillary artery, between the tumor and the capillaries; this was accordingly done by M. Dupuytren, June 12, in the usual manner. The ligature consisted of three threads; and on tightening it the pulsation in the tumor was much increased, and the first twenty were very irregular. The pulse having risen he was bled in the evening (one palette). Next day he felt weak, but the pulsation in the tumor had not diminished, though it was less tense. In the evening the tumor seemed rather less. 15th, no particular change. 16th, the tumor decidedly less; patient's state satisfactory. 17th, the wound dressed for the first time; some scarlet blood on the bandages, and some clots within; patient bled again (two palettes). In the evening, bandages soaked with blood; patient bled (three palettes). Ten at night, blood still exuding; (bled to two palettes.) 18th, slight oozing of blood from the wound, arrested by pressure; much general disturbance. 19th, extremely weak; bled again (one palette). 20th, increasing debility. During the following night he died.

Autopsy.—The right arm œdematous and livid; the points of the fingers black. Hepatization of right lung, with marks of recent effusion of false membrane. Heart very large, flaccid. Aorta much dilated at its origin; diminishing towards the diaphragm; inner surface red, with cartilaginous patches, and some spiculae of bone; a few erosions. The subclavian dilated immediately at its origin, so as to form the aneurismal sac. The tumor was situated beneath the clavicle, and had in a great measure destroyed the first rib. The walls of the sac, inwards, upwards, and outwards, sufficiently resisting, but at some points beneath the lungs formed its parietes. The cavity of the aneurism contained merely a recent coagulum, in no degree adherent. The vertebral, internal mammary, and inferior thyroid arteries, obliterated. The axillary healthy at the point where the ligature was applied, and containing an inconsiderable clot above it. At the point of ligature an opening in the artery was perceived, *probably* made during the dissection; besides, several of the pupils had pulled the ligature before the examination was begun, and these *tractures* were certainly sufficient to have torn the artery. The ligature had not entirely divided the internal membrane. The rest of the arterial system was healthy. The di-

gestive and urinary apparatus presented no lesion. The brain, cerebellum, and its dependencies, were not examined.

Now if we consider the cause of this man's death with a little more attention, we shall observe, in the first place, that the pulsations, immediately after the ligature was applied, became extremely strong: yet rupture of the sac did not take place, although its parietes were greatly attenuated in several places. Two days after the operation the pulsations were feeble, and the tumor was no longer calculated to excite alarm. The patient found himself pretty well up to the fifth day, when an hæmorrhage ensued, which, though not considerable, gave much uneasiness to the surgeon. The cause could not be ascertained: it was at first thought that the loss of blood could be traced to the sac or the axillary artery; but there was more reason afterwards to suspect that it arose from some vessels of small calibre: nor did the examination after death determine the question.

The man was bled frequently: five palettes were taken from him in three bleedings on the same day. It is very probable that this treatment was opposed to the cure of the aneurism; for the plasticity of the blood is essential to its coagulation, and the more the patient is weakened by a sanguineous flow, the less chance there is of this requisite condition taking place. The question is difficult to decide; but it seems probable that those bleedings, though at the moment appearing indispensable, ultimately tended to the fatal result. It might be supposed that the existence of several voluminous branches of the subclavian artery in front of the tumor, or arising from the tumor itself, were prejudicial to the success of the operation. But the autopsy shewed that all these branches were obliterated, as it frequently happens when the aneurism has attained a certain bulk, and when it is situated favourably for compression: and in general, though we may not be sure of the obliteration of those branches, we are not warranted, on this account, to withhold the ligature from between the tumor and the capillaries.

In this case, besides, we should not forget the considerable alterations which existed in the aorta and those of the right lung; for they must have had much influence in producing the fatal termination of the case. But whatever was the cause, the consequence cannot but be deplored. Had the issue been successful, it would have induced numerous trials of the method, and the lives, perhaps, of many unfortunate people might have been saved. Brasdor's method, however, should not on this account be exploded. If new modes

of operating were to be abandoned whenever the first attempts proved unsuccessful, we should be deprived of many excellent resources in surgery. The first time that Astley Cooper tied the primitive carotid, for aneurism of that artery, he failed: the patient died. Mr. Cline, however, tried it again, as did Astley Cooper himself, and other surgeons: and they succeeded. We ourselves lost the first patient on whom we tried the operation for artificial anus, which has since been so successful in several instances; and we publicly declared that the want of success which we met with in this case should not deter us from making other trials of ligature of the axillary artery.

We have seen that the brachiocephalic trunk in the present case, though very voluminous, was sound: it might therefore have been tied, though we know that the two operations of this kind, tried by Mott, in America, and Gräfe, in Prussia, failed. A third, lately practised at Paris, was equally unsuccessful: the patient died of hæmorrhage. These results are not very encouraging: yet, being consistent with ourselves, and reasoning still on the same grounds that we have occupied in discussing the method of Brasdor, we cannot but praise those who, in desperate cases, have had recourse to this bold operation. The propriety, however, of tying the brachio-cephalic trunk, requires to be confirmed by further observation.

ON ANEURISMS WHICH COMPLICATE FRACTURES AND WOUNDS FROM FIRE-ARMS, AND ON THEIR TREATMENT BY ANEL'S METHOD.

Among the causes which give rise to the development of aneurisms, there are two which have met with but little attention from even the most expert observers: I mean fractures and wounds from fire-arms. It can be readily understood how the splinters of a broken bone, or how a ball or other projectile discharged by gun-powder, can originate an aneurism, by slowly altering or even destroying the coats of an artery. It would even seem, on reflecting upon the multitude and infinite variety of fractures and wounds from fire-arms, that these sort of aneurisms ought to be frequent. Yet we scarcely find in the books a single example of the sort; whether it is that such cases are not very common, or, which is more likely, that on this point, as well as many others, the attention has need to be awakened, in order to seize even the most ordinary appearances. J. L. Petit, in his work on the Bones, mentions one case; and since his time, writers on the same subject have not failed to inform their readers that aneurism is one

of the accidents which may supervene on fracture: but none of them cite a case. M. Boyer only gives the case that I communicated to him fifteen years ago. But a pretty considerable number of cases of the sort have come under my observation since the year 1806.

The general opinion which seems to prevail on the subject appears to be, that we should amputate at once, where we find such lesions. Of three operations, however, of this kind, which were practised in my presence by my predecessor in this place, one only succeeded; and a like result which ensued in other instances did not tend much to encourage us to persevere. I accordingly attempted to treat those aneurisms in a way different from that which was in use up to my time; and the following cases will serve to explain my principles and the methods which I thought myself warranted in adopting.

CASE 1.—*Compound Fracture of the Leg, complicated with Aneurism of the Posterior Tibial Artery—Ligature—Cure.*

Martha-Maria Barbe, aged 62, of a dry fibre, but healthy, while running in the street, on the 2d January, 1809, made a false step and fell. She was immediately seized with a violent pain, attended by a crackling noise, at the bottom of the left leg. She could not raise herself from the ground, and was carried home with difficulty. Nothing was done for her the first night. Next day, the pain continuing, along with the inability to walk, she was taken to the Hôtel Dieu, when I immediately detected fracture of the two bones of the leg, at the union of the lower and middle third of their length.

It was an oblique fracture, accompanied by displacement of the fragments forwards and backwards, by deformity of the limb, and swelling and violent tension of the soft parts. I also found on the back part of the leg, in the thickness of the calf, strong and considerable motions of dilatation and contraction, which could be seen as well as felt: they were, moreover, isochronous with those of the pulse. Compression on the femoral artery caused them to cease, and they re-appeared when that compression was taken off. An aneurism, it was evident, had been formed at the moment of the patient's fall: it was caused by some one of the oblique fragments of bone, which produced a laceration of some artery in the back of the leg—the posterior tibial artery, to all appearance. The case was a serious one, whether the advanced age of the patient was taken into account or the nature and complication of the injury. She was properly dressed, but what further steps were to be

taken was not decided immediately. It occurred to me, that however simple and expeditious a method amputation was to escape from further trouble, it would entail on the patient, not only a painful privation supposing she recovered, but dangers which, in many like cases, had terminated fatally. Ligature of the artery at a distance from the lesion I thought was preferable: it would staunch the blood, put a stop to the pulsations in the tumor, and allow the end of the torn artery to cicatrise. Such, with other reasons, served to persuade me; but the sanction of experience was wanting.

The operation was performed in the middle of the thigh, in the usual manner, and the moment the ligature was fastened the pulsations ceased. A simple dressing was applied: that for the fracture was continued. Now was the time that should determine the fate of the patient: but the heat and sensibility of the limb were not for a moment altered; the circulation continued uninterruptedly, and from the fifth day the collateral arteries about the knee could be seen and felt, by whose development the blood was conveyed to the lower portion of the artery affected. Six days had scarcely elapsed when the volume of the tumor was found to be reduced one-third, and it eventually disappeared altogether. The ligature fell off about the fifteenth day; there was no hæmorrhage, and the wound was cicatrised in less than six weeks.

While matters thus proceeded with the soft parts, nature was effecting the consolidation of the bone: it went on slowly, either in consequence of the obliquity of the fracture or owing to the fragments being bathed in blood, or, in fine, because the ligature had diminished in this quarter the powers of nutrition. The callus, in short, was scarcely begun at the end of the first month; it offered but little consistence at the end of the second; and did not attain the state of perfect solidity until four months had elapsed. The patient then attempted to walk: she was soon able to leave the hospital, perfectly cured of both fracture and aneurism; and at the end of fifteen years we saw her in the enjoyment of perfect health.

There was another case of this description which we lately saw. A man had had a comminutive fracture, and the fragments protruded. Several hæmorrhages took place through the wound, without the possibility of discovering the spot from which the blood flowed. I put a ligature on the femoral artery, as already described, when the hæmorrhages ceased, and the man got well.

Now, with regard to wounds from firearms, complicated with aneurism, I shall

proceed to show, that these do not require amputation any more than fractures so complicated; and that they too may be cured by simply tying the principal artery of the limb. Here are facts to warrant this statement:—

CASE 2.—Aneurism from a Pistol-Shot—Ligature of the Femoral Artery—Cure.

M. de Gombaut, captain of a troop, and aide-de-camp to one of our most distinguished lieutenant-generals, on the 10th February, 1818, received a shot from a horse-pistol through the upper part of his right leg, from before backwards, and from the outside inwards, passing between the tibia and the fibula, which it slightly crushed. A very violent hæmorrhage occurred in a moment, which was presently arrested to some extent by a compressive apparel applied to the two orifices of the wound. The patient was taken home; the leg swelled, and became the seat of severe pain; to which succeeded a troublesome numbness. An aneurism was forming, which every day grew larger and more distinguishable.

In spite of the application of the compressive bandage, and the tourniquet of Petit, an hæmorrhage took place about the thirteenth day of the wound; it recurred frequently afterwards, and weakened the patient greatly. I was now called in by the physicians of the patient.

The foot and leg were violet, tumefied, cold, and benumbed. In the upper part of the leg there was a swelling, with tension, and pulsations isochronous with those of the heart. The orifices which the ball had made were over this tumor, and each of them was stopt with a clot of blood, which was violently shaken at every impulse, and seemed likely at every moment to be thrown out. There could not be a doubt that destruction of one or more of the great arteries in the ham had here taken place. The case was urgent. After weighing the advantages and disadvantages of the ligature applied immediately to the extremities of the divided vessels, and of amputation, the mortality of which is not less than a fourth; encouraged besides by the success of Me. Barbe's case, I proposed ligature of the femoral artery, which was at once agreed to.

The operation was performed in the usual manner; the limb being then semi-flexed, and reclined outwards on a pillow, charpie was laid on the orifices of the wound in the leg. The aneurismal tumor was covered with thick compresses soaked in Goulard water; and the rest of the leg and foot was kept warm. Neither the heat, sensibility, or motive power of the parts was for a moment altered. The after-

treatment consisted of some antispasmodics, to calm the nervous state of the patient; and attention was paid to strict regimen, for fear of the occurrence of inflammatory symptoms—to posture and repose, to prevent the draggings and lacerations of the parts—to the frequent application of emollients about the aneurismal tumor—of warm bodies about the foot and leg, to maintain the circulation and life in the parts—then by systematic dressings night and morning, to remove the pus and blood with which the limb was embarrassed. Thus was the patient treated up to the 20th day, when the ligature of the femoral artery came off. At the end of six weeks all the wounds were completely cicatrized; the limb was then a little swollen and discoloured, but by degrees these appearances vanished; and three months after his accident M. de Gombaut walked as well as ever he did.

The ligature, by suspending the circulation in a divided vessel, the solution of continuity of which had given rise, all at once, to an internal and external hæmorrhage, allows time for inflammation to set in and a healing process to take place in the wounded vessels, to render their extremities impermeable to the blood which the anastomoses in their neighbourhood might carry to them. This sort of obliteration we should naturally expect to take place more readily and certainly after wounds from fire-arms than any other. It is well known that one of their most remarkable effects is that of causing the orifices to shrink up, and to coagulate the blood in their extremities; thus rendering them impermeable to this fluid.

Since M. Gombaut's case, I have met with others which served to confirm me in the treatment which I adopted with this officer. Some would maintain, it is true, that the method is not suitable for primitive false aneurism, whatever be the situation of the artery; assuming that the mode of cure of the lower extremity is different from that of the upper. There is not, they say, so much contraction of the lower orifice as of the upper; the contraction, besides, does not last so long, and there is less clot formed: and, adding example to precept, they do not hesitate to divide the considerable muscular fascia which covers the upper portion of the cubital artery, to tie in this place; and in the same way they put a ligature on the peroneal artery, dividing the muscles of the calf. Now, without wishing to detract from the merit of such proceedings, we will simply state, that, in the case of M. Gombaut, it was impossible, in the first place, to know whether the injury was done to the anterior tibial artery or the posterior tibial, or to

the peroneal, or in fine the popliteal, or indeed to several of these vessels at once; and, in the second place, to determine the height at which this lesion might be found. Thus, even though in this case we were not to take into account the depth of the vessels, their relations with the bones, the muscles, and the nerves, the ligature of the two ends was impracticable. This is what has been stated in the article *Aneurism*, in the 2d edition of the *Dictionnaire*, in 21 vols.—namely, that the search for the point of lesion of the artery presents sometimes so many difficulties that we are generally obliged to have recourse to a single ligature, placed at some distance above the wound.

In conclusion, it is my decided opinion that, in lesions of an artery of a limb in consequence of fracture or a gun-shot wound, ligature of the main trunk at some distance from the seat of the injury, and between that seat and the heart, ought to be substituted for ligature of the two ends of the vessel, which is often impracticable, and for amputation, which, up to our time, had been considered as the sole resource in injuries of this nature.

CHEMICAL EXAMINATION OF THE CONTENTS OF THE STOMACH,

In a Case of suspected Poisoning :

BEING A MEDICO-LEGAL REPORT MADE TO THE
FRENCH AUTHORITIES, BY

MM. OLLIVIER D'ANGERS, GREMILLY,
BARRUEL, AND CHEVALIER*.

IN compliance with the request of M. le Procureur du Roi, we met in the theatre of the Practical School on the 16th July, when we unsealed an earthen jar containing the stomach and bowels of the *Sieur G.* who had died the day before. The contents, being transferred into a glass capsule, were taken into the laboratory of the school. On proceeding to examine their physical properties, we could not help being immediately struck with their excessively disagreeable putrid odour. Their colour was that of *café au lait*; and the liquid matter was mixed with hard lumps resembling meat, which had been cut up and swallowed without previous mastication. Those lumps on being repeatedly wash-

* From the *Annales d'Hygiène Publique* for July.

ed and examined carefully proved to be chicken's flesh.

The fluid contents, being now mixed with the washings of the meat, were passed slowly through a filter: a portion of it treated with hydrosulphuric acid in excess gave no indication of the presence of poisonous matter of the mineral kind.

The remainder, being put into a clean capsule of glass, was exposed to the process of evaporation by a gentle heat: it presently formed a coagulum, in the shape of very large flakes, of a greenish grey appearance, much like those which are found floating on evaporated liquor that contains altered blood. Separating the flakes by filtration, we once more applied to the fluid residue a gentle heat, which reduced it to the consistence of a soft extract. The odour of this extract was highly offensive: its taste was saline, but without any thing nauseous or bitter. On diluting it with distilled water, a liquor of a fine brown colour was procured, part of which was tested by hydrosulphuric acid, hydrochlorate of barytes, and sulphate of soda. But no indication was afforded of the presence of any metallic poison.

The greater part of this liquor was once more reduced to the consistence of an extract: during the evaporation, a saline pellicle covered the surface of the liquid. Strong alcohol (40°) was now applied, and the spirituous solution evaporated again to one-half. Water was then twice added, and the evaporation renewed, with a view to drive off the alcohol altogether, without disturbing the matter dissolved.

From this last evaporation a yellowish brown extract was obtained, the taste of which was neither bitter nor disagreeable. The addition of water dissolved it only partially, leaving whitish flakes for a residue. The watery solution treated with iron struck no red colour, as neither did another portion of it which was treated with pure nitric acid; but on the contrary, its original colour was sensibly diminished in intensity.

The portion which was not dissolved by the alcohol, and which consisted of salts, was treated afresh with distilled water: the solution filtered and evaporated in a glass capsule produced a mass of salt composed principally of phosphate and hydrochlorate of soda. The

great abundance of the phosphate recognized in this saline residuum, and which is not usually observed in the examination of analogous liquids, induces us to believe that the *Sieur G.* must have taken phosphate of soda during or after his repast.

The greenish grey flakes, separated from the liquor during evaporation, and collected on a filter, were now put into a porcelain crucible and exposed to the action of heat, until incineration took place. The cinders were of a yellow colour—a colour which disappeared on their cooling, but which was restored on heating them again. Treated with distilled water, the cinders yielded a saline liquor, which by the action of hydrosulphuric acid, muriate of lime, and nitrate of silver, was not found to contain any poisonous saline substance: the only products were the carbonate, the hydrochlorate, and the phosphate of soda.

The portion which remained undissolved by the water was treated with hydrochloronitric acid by heat: the filtered solution was yellow, but after evaporation in a glass capsule, in order to drive off the excess of acid, the residue was colorless. Diluted with water, and treated with an excess of hydrosulphuric acid, no colour was produced; whence we inferred the absence of any mineral substance that could be prejudicial to health.

Those matters which, after the first filtration of the contents of the stomach and bowels, had remained on the filter, were now put, along with the filter itself, into a porcelain crucible, and placed in a furnace of charcoal. A red heat was produced, and continued till the incineration was perfect. Red and yellow cinders were the result; but the yellow colour which was observable while the cinders were hot, disappeared when they cooled, re-appearing again when heat was once more applied.

All that was soluble of these cinders in distilled water was now obtained, and the saline solution exposed to various reagents. The results were carbonate, hydrochlorate, and phosphate of soda; besides some traces of a soluble sulphate. We were thus persuaded that the liquid contained no poisonous metallic salt.

The insoluble residue was now treated with hydrochloronitric acid, and exposed to heat: the filtered solution was yellow.

When evaporated in a glass capsule, in order to expel the excess of acid, and water added, we ascertained by the test of hydrosulphuric acid in excess. that there was no metallic salt in the solution.

From these several facts and experiments, we infer that the matters contained in the stomach and bowels of the *Sieur G.* contained no substance of a mineral or vegetable nature that was poisonous. We cannot, however, refrain from repeating, that the enormous quantity of phosphate of soda which we found during our search, strongly fixed our attention, inasmuch as we never before observed so large a quantity of the salt in any animal fluids submitted to our examination. We are therefore induced to conclude that this salt must have been taken by the deceased, though there is no documentary evidence to that effect. We regret that the matters vomited, if there were any, had not been collected, as they might have been examined to see whether they also contained any quantity of the phosphate. Negligence in securing the matters vomited by persons supposed to be poisoned (and it is a fault of frequent occurrence) cannot be too much reprehended; for those matters may contain the greater part, if not the whole, of the poison administered.

Paris, July 27.

PRESENCE OF UREA IN THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

ALLOW me to call the attention of your readers to the objections which have been raised against the existence of urea in the blood. On examination it will appear that these objections are founded on the two following reactions, which are said to simulate those produced by urea. 1stly, A crystallization produced on the addition of nitric acid to the peculiar fatty matter of the blood. 2dly, A peculiar smell which is evolved on the addition of the same acid to the animal matter of that fluid. Now if these two be admitted as facts, still the doubts of your correspondents are valid, only on the supposition that these tests have been used exclusively in researches on this subject, which would be a most unwar-

rantable presumption. Perhaps the unsuccessful attempts at discovery have led to the denial; but thus to make the subject a matter of authority, would be placing themselves in opposition to a list of men so eminent, that I should suspect them of an absurd degree of vanity, and I would rather accuse them of thoughtlessness, in treating a subject already so ably investigated. The most important, however, of the reactions adduced by these gentlemen (viz. the peculiar action of nitric acid on the fatty matter of the blood) I do not scruple to deny, and shall be contented to leave the urinous odour to deceive chemists who are satisfied by using their olfactory organ to the complete exclusion of all other senses.

I cannot accord with the ideas of these gentlemen regarding nomenclature; but agree with them in doubting the existence of any such acid as the leucic, which ought to convince them that the term nitro-leucic is unequivocal, whereas nitro-stearic acid might be regarded either as a compound formed by the combination of stearine and nitric acid, or stearic acid and nitric acid: the most natural mode of understanding it would certainly be the latter. I should wish to remind your authors of the exceedingly minute portion of fatty matter contained in the blood, and the almost inappreciable proportion of stearine entering into its composition. The crystallization produced by the addition of nitric acid to an aqueous solution, has been acknowledged as a satisfactory test in your last number; which in fact is allowing that urea has been demonstrated in the blood, since your authors are aware that I have successfully employed this mode of proof when experimenting on the subject.

By the insertion of these remarks you will much oblige

Your obedient servant,
G. O. REES.

Guy's Hospital, Sept. 18, 1833.

THE APOCYNUM CANNABINUM, AND ITS MEDICINAL PROPERTIES.

To the Editor of the Medical Gazette.

SIR,

HAVING received from my medical friends in the United States repeated accounts of the powerful virtues of this plant, and

lately a very full dissertation on its history, properties, and effects on the human body, published by an intelligent young physician, Dr. John H. Griscom, of New York, I think your pages will greatly assist me in making known to the medical public of this country the physiological power and usefulness of this valuable plant; and I, moreover, trust its use in this country will be attended with equal success to what it has been in the hands of our transatlantic brethren.

With this view I shall select only such parts of Dr. Griscom's dissertation as will serve to indicate the plant botanically, and to make its properties and practical effects generally known, so that its administration may be readily undertaken.

The plant belongs to the class *Pentandria*, order *Digynia*, of Linnaeus; and to the natural order *Contortæ Apocynæ*, of Jussieu. Its *synonyms*—Indian hemp, dog's bane.

General Characters.—*Apocynum*, calyx very small, 5 cleft. *Corolla* campanulate; border with 5 short, spreading, revolute lobes. *Anthers* sagittate, connivent, cohering to the stigma in the middle. *Styles* obsolete. *Stigma* dilated, and conical at the apex. *Follicles* 2, long, linear. *Seeds* comose.

Specific Characters.—*Ap. Cannabinum*. *Stem* upright, herbaceous; *leaves* oblong, tomentose beneath; *cymes* lateral, larger than the leaves.

Description.—The roots are perennial and creeping; the stems are brown, and about two feet high; the leaves smooth, in pairs; it abounds in a milky juice. It is seldom admitted into gardens, except for the sake of variety. It flowers from July to September, and is a native of Virginia and Canada. It is propagated by parting the roots in March, and is hardy enough to thrive in the open ground; but the soil should be light and dry. The stems decay to the roots in autumn, seldom ripening their seeds. The bark of the stem, when dry, is very fibrous, and may be peeled off in strings. The Indians of North America prepare the stalks as we do hemp, and make twine, bags, fishing-nets, and linen for their wear.

The root, which is very tortuous, is the only part employed in medicine. It consists of two distinct portions: the ligneous part is of a yellowish-white colour, possessing a considerably bitter

taste, and some odour. The cortical part is of a brown colour, rough externally, white and smooth within. Its taste is intensely bitter, rather nauseous; odour strong and unpleasant.

Chemical Properties.—Water dissolves the greater part of the colouring and bitter materials of the root, of which the cortical part contains by far the larger quantity. From twenty-two analyses carefully executed by Dr. G. it appears the root consists of, 1. tannin; 2. an acid, probably the gallic; 3. gum; 4. resin; 5. wax; 6. fecula; 7. bitter principle, or *apocynin*; 8. colouring matter; and an appreciable quantity of caoutchouc.

Medical Properties.—When taken internally, it appears to have four different and specific operations on the system: 1st, as an emetic; 2dly, as a purgative; 3dly, as a diuretic; and 4thly, as a sudorific. Its first operation, when taken into the stomach, is that of producing nausea, if given in sufficient quantity; and if this is increased, vomiting will ensue. It very soon evinces its action on the primæ viæ and bowels, by producing copious, feculent, and watery discharges, particularly the latter; which action, when once excited, is very easily kept up by the occasional administration of a wine-glassful of the decoction. Its next consecutive operation is its sudorific effect: copious perspiration almost invariably follows its exhibition, to which is attributed the powerful influence it exerts on the various forms of dropsy. Its diuretic effect does not appear to be so great in many instances as in others.

Dropsy is the only morbid affection for the relief of which the powers of the plant have been as yet brought into successful requisition. Its very active and often violent operation, would seem to preclude its use in diseases of much febrile or inflammatory excitement. It is best exhibited in the form of decoction, made by boiling from two drachms to an ounce of the root in three pints of water, down to two; of which a wine-glassful may be given twice or thrice a day to an adult.

Of seven cases detailed by Dr. Griscom, which were all successfully treated by the medicine, I will only succinctly transcribe two of the last.

CASE V.—An athletic and stout Englishman, a cook, of a sanguine temperament, and aged about 50, had always

enjoyed excellent health till within a few months of his illness here mentioned, when he was attacked with inflammatory affections of his chest and liver, for which he was treated at Washington by large depletions, mercurials, &c. When first seen professionally in New York, he was found seated in an armed chair, leaning across the back of a small one, pallid, breathing with difficulty, scarcely able to answer the questions put to him, from great oppression in the chest and abdomen, and general anasarca. He had not been able to lie down in his bed for three weeks. There was no pain, with the exception of a slight uneasiness in the right hypochondrium, where the liver was evidently enlarged. Pulse slow, and intermittent. He was immediately put on the use of the Indian hemp, which was continued in this almost hopeless case for three weeks, without any other internal remedy; after which period he was enabled to return to his usual employment, and actually cooked a dinner for thirty people almost without any assistance. The formula used was

R Rad. Apoc. Can. Contus. Bac. Junip.
a. ℥j.; Aquæ, Oijj.; coque leni igne
ad Oijj.; cola et adde Spir Junip. ℥iv.

of which a wine-glassful was taken three times a day, diminishing the quantity if he was too much purged or vomited.

The other case selected is that of the daughter of Professor Renwick, of Columbia College, New York. She was aged about 16 months, and after ten days of general fever, with determination to the chest and head, the sutures of the head became opened, the forehead projected considerably more than before, and the sight of one eye became totally lost, while the other retained but little sensibility. A constant involuntary motion of one arm and leg remained for 36 hours. In this very advanced stage of cerebral effusion, and after all ordinary means had been tried by the attendant physician without avail, recourse was had to a decoction of the apocynum cannabinum, which was prepared by dropping in pieces of the root into a coffee-cup, until it was nearly full, then covering it with hot water, and setting it by the fire for an hour. Of this, half a tea-spoonful was given every hour;

and in 18 hours a marked and improved change had taken place in the symptoms. The urinary organs began to act freely; the sight of both eyes became perfect; the blisters that had been applied, and had not even caused redness, rose, and gave out a copious discharge; the stupor, which had allowed the nauseous medicine to be given, had disappeared, and its administration was forcibly resisted. The quantity was, however, diminished, and continued for a fortnight occasionally, when a perfect recovery was accomplished.

In addition to the above-condensed notice of Dr. Griscom's dissertation, I may state, that I personally received, in 1830, from that eminent surgeon, Dr. Mott, of New York, very high testimonials of the sanative powers of the plant in dropsy, along with a specimen of the dried shrub at the time. He seemed to classify its effects with those of colchicum, but thought that they were of a more variable character, exhibiting themselves less on the kidneys, and more on the bowels and skin. So much were its merits appreciated at New York by medical men at that time, that the British Consul was induced to send a quantity home to the medical attendants of his late Majesty for his relief, but it arrived, I understood, subsequent to his decease.

Chloric Ether—New Remedy in Spasmodic Asthma, &c.

I may here take the opportunity of mentioning, that there is another article brought into medical use by our American brethren, which promises to be of service in spasmodic asthma, and in adynamic states of the nervous system, with or without fever; not forgetting that it is one of the most agreeable and diffusive cordials we can make use of. It is one of the new products of the chemical kingdom, called *chloric ether*, resulting from one of the many combinations in which the simple elements of ether are disposed to unite with different proportionals of chlorine. It may be easily procured for medical use by distilling over, in a glass retort with a long neck kept very cool, dry chloride of lime fully saturated and covered over with alcohol. The liquid thus driven over is a solution of a new substance, the chloride of carbon in alcohol. It is perfectly limpid and pure, having a

fragrant ethereal smell, with a faint yet pleasant perception of chlorine. Its most sensible property is, however, its delightfully *sweet* and vinous taste, and when diluted with water, forms one of the finest cordials in any materia medica.

I have used it frequently in doses of about half a drachm, according to its strength, and from my short experience I am disposed to think it will be of more positive benefit than any of the muriatic or sulphuric ethers, and well worthy the attention of the medical practitioners of this country.

I am yours, &c.

J. BLACK, M. D.

Bolton, Sept. 20, 1833.

RECAPITULATION OF SURGICAL DOGMATA ;

As taught by the PROFESSOR OF ANATOMY AND SURGERY in the University of Dublin.

1. ALL vital phenomena are the result of sensibility in its different modes.

2. The visible phenomena of inflammation, and of most surgical diseases, depend immediately on the state of the minute arteries, as organs of circulation and secretion.

3. That arteries possess no direct sensibility as to injuries inflicted on themselves; they are not endowed with any of the properties of muscles, but have a positive power of dilating and contracting, according to the different states of feeling, or of impressions, made on the nerves. Their middle state of contraction is their healthy condition, and the one most suitable to their functions as organs of circulation and secretion, and the only one necessary to the reparation of injured parts.

4. That the middle state of arteries is most consistent with a natural state of feeling in the nervous system. When they are dilated in erectile tissues, the sensibility of the nerves is augmented; when they are dilated in inflammation, their circulation is obstructed and their secretions are suspended, consequently the feeling in the nerves of the part amounts to pain; when they are contracted below the medium state, their sensibility is diminished; and when they are contracted in a degree not to admit blood, the sensibility of the nerves is extinguished.

5. That inflammation in any degree, so far from being necessary to the reparation of parts, always interferes with it.

6. That the term "adhesive inflammation" is erroneous, inasmuch as adhesion and union can take place without pain, heat, swelling, or redness, as is witnessed in many wounds, and particularly in the common operation of phlebotomy, which is a wound of skin, cellular substance, and venous tissue, which last, when inflamed, produces the most mischievous consequences.

7. That the effusion of lymph is not an inflammatory, but a conservative process, although the adhesion and union of some parts that are naturally free may be attended with much subsequent inconvenience, as in the iris and some serous cavities.

8. That the especial care of the surgeon should be, in all cases, directed to remove or prevent inflammation.

9. That this is to be accomplished by such means as directly remove the dilated state of the small arteries, or as indirectly restore the natural state of the arteries, by acting on the sensibility of the nervous system, or the nerves, in the inflamed or injured part.

10. That if the sense of injury or of pain in the inflamed parts be removed, the arteries return to their natural state, and exercise only their natural functions.

11. That under this condition the motive to suppurate, granulate, or even to throw out more lymph than is necessary for reparation, is removed; and large open wounds will coalesce, by the contracting process alone, in the same manner that is observed in the lower classes of animals, in whom no inflammation can be excited.

12. That the most effectual means of acting on the sensibility of the nerves are, easy and elevated position, freedom from restraint or constriction, avoidance of uneasy motions, placing the part and adjoining skin in the most agreeable state of feeling, by the means of moisture; keeping it in contact with the softest and lightest external substance; modifying their temperature in the way that gives the greatest ease and comfort to the patient's sensations at the time; also, by putting the two great sentient surfaces of the body, the skin and mucous membrane, on which the nerves terminate, in a natural and easy state, by breathing a salubrious atmosphere, and by influencing the whole nervous

system by tranquillity of mind and the feelings of hope.

13. That surgeons have always attended partially to these circumstances, but from not studying sufficiently the laws of sensibility, and the powerful influence which the nervous system has over the arterial, they have hitherto neglected to employ it, and have been led to place undue confidence in means which they have supposed to act more directly and medicinally on injured or inflamed parts.

EHRENBERG ON THE INFUSORIA.

To the Editor of the Medical Gazette.

SIR,

GLANCING over one of your numbers on our (Royal College of Physicians') table, I was surprised to see a paper, an apparent analysis of Professor Ehrenberg's mode and discoveries on the Infusoria, from an American journal, as if such were not already before the British public.

In justice to my son, Dr. Meredith Gairdner, I cannot let this pass unnoticed, who has this merit, as well as that of since being the author of a distinguished little essay on thermal and mineral springs; but who is now occupied in Western North America, on the shores of the Pacific, on professional and scientific pursuits, in the service of the Hudson's Bay Company.

Ehrenberg first propounded his discoveries on the Infusoria at the annual public meeting of scientific men, held at Hamburgh in September 1830, at which my son was present, and had the good fortune to get personally acquainted with this eminent man. Soon afterwards, meeting him by appointment at his home in Berlin, Meredith received from the Professor much attention: the investigations and experiments were largely gone into: see a short notice of some of them mentioned soon afterwards in Professor Jameson's journal here (Edin. New Philos. Journ.), in one of the numbers of 1831.

On his return home in the fall of this year, my son drew out, at Professor Jameson's and others' request here, an analysis of what he had seen and learnt of Ehrenberg's methods and discoveries,

which appeared in the Edin. New Phil. Journ. of Oct. 1831, and Jan. 1832; and which was their first announcement in this country.

Trusting that your candour will do justice to this ardent, and enterprising, and already somewhat distinguished youth, and also to the scientific character of our common country, I have the pleasure to be, with all due consideration, sir, your most obedient and faithful servant,

EBEN. GAIRDNER, M.D.

Fellow of the Royal College of Physicians.

3, Argyll Square, Edinburgh,
8th August, 1833.

[It so happened that our attention was not directed to the paper till we met with it in the American Journal.—ED. GAZ.]

ST. BARTHOLOMEW'S HOSPITAL

—DECLARATION OF MR. SKEY.

To the Editor of the Medical Gazette.

SIR,

I TRUST I shall be acquitted in the judgment even of my enemies, of an undue desire to obtrude myself on public attention. I would cheerfully have forborne the necessity of repudiating the imputation of indifference; but I cannot consent to repose my claims to the confidence of my professional brethren on anonymous advocacy. With the introduction of the subject to the public I had nothing to do, though I do not affect to regret, that what have been called my wrongs, have attracted public attention, while I affirm that I should have preferred any other mode of equitable arrangement to the alternative of placing myself in a situation in which I may by possibility become obnoxious to the charge of appealing unnecessarily to the succour and support of public opinion.

I have performed the duties of Demonstrator to St. Bartholomew's Hospital during eight years, and I have every reason to believe that I obtained the good opinion of the teachers in each department of professional instruction; having addressed a class annually increasing in number—pupils whose regularity of attendance, and whose uniform propriety of conduct during the

hour of lecture, and whose devotion to the duties of the dissecting-room, were as honourable to them, as they were agreeable to me.

These facts may be fairly admitted as proof that the duties of my office were not neglected by me; and I hope I have some claim on the attention of my professional brethren, and some right to call on public opinion, to determine both the justice and the validity of my unceremonious exclusion from my office. I do not solicit the sympathy of the profession; but I call upon you, as an impartial organ of its sentiments, to support me in obtaining the inquiry.

To the first count of the charge whispered against me that I was "factious," I plead not guilty. I assert positively on my honour as a gentleman, that I was totally unprepared for this most arbitrary exercise of assumed authority, and that in my daily intercourse with the gentleman at the head of the Anatomical Department of the School at St. Bartholomew's, there had been no expression, no feeling, manifested by me which could have compromised my character, as a faithful member of the school, nor that could consistently with my ideas of right or wrong have warranted the step that gentleman has adopted. If on inquiry the unprecedented conduct of the Professor of Anatomy can find its justification in any neglect of duty;—if he can establish to the conviction of an impartial tribunal the necessity for my removal;—if public advantage demanded the sacrifice, and not private consideration;—if he can exhibit to public view one shade of the generous or the just in his conduct or motives;—I will without complaining allow judgment to go by default. But if, on the contrary, I can prove that I have invariably discharged my duties with the ability that has obtained for me an honourable reputation—that has contributed in some degree to raise the anatomical reputation of the school;—if I can prove in my intercourse with Mr. Stanley, without prejudice to my own self-respect, I never lost sight of the consideration to which, as my principal *under other authority*, he might fairly be entitled, I presume I shall make out a case of aggression on his part, that will ensure me the support of the press, the profession, and the public. Nevertheless, I deny under any

and all circumstances Mr. Stanley's right to exclude me from the office.

I am, sir,

Your most obedient servant,
FREDERIC C. SKEY.

Southampton-Row, Sept. 25.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ lueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE

LIVERPOOL INVESTIGATION.

PENDING the late inquiry into the conduct of Dr. Baird, we studiously avoided offering any remarks which might bias the reader's mind one way or the other on the subject; and it was not without feelings of strong disapproval that we noticed the foolish zeal with which some of our contemporaries took up the matter, to "vindicate," forsooth, a man against whom no regular accusation was laid, and to perplex the affair between Dr. Baird and the Liverpool Infirmary with their mawkish sentimentality about the honour, and dignity, and so forth, of the whole medical profession.

We were by no means inattentive observers of the progress of this vexatious affair; but we were, at the same time, far from presuming that our knowledge of the facts was sufficient to warrant our giving a decided opinion on them—especially when we understood that an investigation was being held on the whole of the evidence by a competent neighbouring tribunal. The officers of the Manchester Infirmary, on being applied to by the general voice, as the most fit and proper persons to take judicial cognizance of the case, we were glad to perceive, did not shrink from the in-

vidious duty; and the result of their labours is a decision with which, we think, all fair and moderate men ought to be satisfied: of course a few snarlers may be found to complain that it expresses either too much or too little, according as it may seem to suit their several little purposes. The verdict from Manchester is the following:—

Report on the case of Dr. Baird, adopted at a Special Meeting of the Medical Committee of the Manchester Royal Infirmary, on the 10th of August, 1833.

“We, the undersigned physicians and surgeons of the Manchester Royal Infirmary, having carefully and maturely considered the several documents transmitted to us by the Committee of the Liverpool Infirmary, relative to the conduct of Dr. Baird, in making a private examination of the female, S. P. V., and likewise those forwarded by Dr. Baird, in explanation of the circumstances which led him to make such examination, are unanimously agreed—

“That owing to the conflicting nature of the medical evidence, it is impossible to arrive at any satisfactory conclusion as to the question, whether an examination of such a particular nature was or was not essential to the perfect understanding of the disease of S. P. V. But we are also satisfied, from an examination of the affidavits of the young woman and her parents, sworn before T. C. Porter, Esq. and in the absence of all evidence of impure or sensual motives, that no imputation rests upon the moral character of Dr. Baird, for his conduct on this occasion.

Signed,

“EDMD. LYON, M.D.

“JAMES LOMAS BARDSLEY, M.D.

“J. DAVENPORT HULME, M.D.

“J. A. RANSOME.

“RICHARD THORPE.

“WILLIAM JAMES WILSON.

“THOMAS TURNER.”

On the strength of this decision, the propriety of abandoning all further inquisitorial proceedings has been resolved on by a general meeting of the Trustees of the Liverpool Infirmary; a resolution in which we most heartily concur;

and having said so, let it not be supposed that we are inconsistent with ourselves in penning the remarks that follow. We have no wish whatever to moot the question anew: inquiry is not now our object. We merely proceed to offer a few observations which appear to us to arise naturally out of the circumstances.

The first thing that strikes us, in our review of the whole transaction, is the mischievous officiousness in which it originated. A hearsay, a rumour, had got abroad, that Dr. Baird had exceeded the bounds of delicacy in his examination of a female patient—a patient, be it observed, not of the Infirmary or Asylum to which he was attached, but a private patient, who waited on him at his own house. Of this rumour a reverend gentleman (the Rev. Mr. Monk), with an astonishing degree of charitable alacrity, caught hold, and carried it to an official quarter—the Committee of the Liverpool Infirmary; and such an impression did he make by his zealous representations, that a sub-committee was immediately appointed to inquire into the alleged impropriety of Dr. Baird's conduct: nor had the said Mr. Monk—the reporter of the hearsay, the preferrer of the imaginary charge—any scruple whatever in permitting himself to be named one of the three members of the sub-committee! The gross informality which thus marked the outset of the proceedings, one would have thought too palpable to be followed up by men of the commonest understandings: but it appears it was not so—a rash and foolish step was taken, and it must be pursued, whatever mischief might be the consequence. An inquisitorial scrutiny into a professional man's character was forthwith set on foot, grounded on the mere shadow of an accusation!

But, anomalous and unwarrantable as was this commencement of so serious a business, perhaps a counterpart

for it may be found in the extraordinary conduct of the accused. Dr. Baird not only tamely acquiesced in all that was going forward, but, with an indiscretion rarely to be matched, administered fuel to the fire in which it was designed to test, if not to consume, him. His judges questioned him about his acts—he informed them of his very thoughts—thoughts which, however defensible, if confessed to a professional tribunal, were but gratuitous, nay, explosive *matériel* for the parties to whom they were uttered. The hearsay was powerfully strengthened by the “reflections” which the accused confessed were passing through his mind at the time that he was alleged to be doing what was conceived improper. He acknowledged that he made an examination of the sexual organs of his patient: but this was not all; he went farther, and admitted, that while doing so for an essential purpose, he indulged in certain other considerations which were altogether unconnected with the proper object of his examination. Of this gratuitous admission, we understand that the Doctor afterwards repented, but it was too late. The spark which threatened him at first, was now fanned into a blaze by his own imprudent candour. It is idle to argue that a confession thus voluntarily given should not be used to criminate the party giving it: no principle in our criminal jurisprudence is better understood than that an accused person is not bound to give evidence which may tend to criminate himself; but it is equally well established, that if such evidence be voluntarily tendered, it is available for all the purposes of the accuser.

It is beyond a doubt that Dr. Baird, in this matter, was treated with more than ordinary hardship. The charge brought against him (if charge it can be called) was of a very undefined description—one with which it was almost impossible for him to grapple. In the language of the ac-

cuser, he (the Rev. Mr. Monk) had heard a rumour that Dr. Baird had “taken an improper advantage of his professional privilege, in the examination of a young female.” We shall transcribe the spirited remarks of the *Liverpool Medical Gazette* on this point. “What,” says the Editor, “does this ‘improper advantage’ imply? Is he accused of seeking the gratification of some sensuality? Is he charged with having committed all those acts which this ‘improper advantage of his professional privilege’ would comprehend? In point of fact, Dr. Baird was, by implication, accused of every deed which depravity could suggest, and yet openly charged with none. * * * If the ‘members of the Committee’ thought themselves called upon to impugn the moral conduct of Dr. Baird, they should have done it in a proper, manly, overt manner, as devoid of ambiguity and vague insinuation, as their own participation in the affair should have been free from the suspicion of pique, jealousy, malice, or uncharitableness.

“If Dr. Baird,” continues the same writer, “had consulted his own dignity,—if he had respected the feelings belonging to his professional association,—how very different would have been his conduct from that which it proved to be, and how very different would have been the result of the investigation! Instead of proceeding to extremes, that have compromised the character of the Committee of the Liverpool Infirmary, the functions of the Sub-committee would have soon ceased,—the Trustees of the Infirmary have been spared the unpleasant part they have been called on to perform,—and Dr. Baird would not now be a sufferer from the impertinent and ungenerous interference of a self-organised, arrogant, and unjust inquisition. Why did not Dr. Baird, in the commencement, deny to the Committee of the Infirmary all right of investigat-

ing his *extra-official* conduct? Why did he not repel with merited contempt these attempted innovations on his privacy? Did he not see in one of his judges his accuser? Why did Dr. Baird condescend to explain away a proteus-like charge that was no sooner deprived of one form than in another it rose to the attack? However he may have been deluded into the use of candour, he ought surely to have insisted on his accusation being reduced to a less general and more definite form, so as to dispossess it of the danger with which it invested every expression, however unimportant, or every fact, however subordinate, to the general context of his explanation. By explaining, Dr. Baird recognized the Sub-committee as the tribunal before which his moral character was to be exposed, acknowledged in it the right of investigating his private transactions, and interrogating his intercourse with his private patients. By an attempt at an explanation, Dr. Baird, by implication, allowed that there was some foundation for the rumour, and by the explanation which he did make, more strongly confirmed this rumour."

On the question of the necessity for examining the female organs at all in this case we do not presume to enter; we can only say with the Manchester reporters, that we have not evidence by which to pronounce decisively upon it. Much we fancy may be said on both sides; and the testimonies which have been brought forward by Dr. Baird on the point may be readily neutralized by the objection, that they are founded on *his* representations, and that they only go to this extent, that if the symptoms of the patient were, as they are stated to have been by Dr. Baird, an examination *was* necessary. The impression, however, on the minds of the accusing party was, that it was an irrelevant and improper proceeding; and, unfortunately,

the avowal of Dr. Baird himself only tended to render that impression permanent and immoveable.

When the proceedings had reached this stage, they had already acquired such an impetus that they could not stand still; neither the Committee nor the Doctor could waive a further advance. On the one side, the officers of a public institution had to deal with their physician, who stood charged with an offence against morals, to which his own inadvertent or too candid avowal had given a colour: on the other, the physician was but too sensible how much his character—his reputation—his good name—would be compromised should he attempt to suppress an ulterior investigation. It was now felt that the good repute of a medical man should be like the chastity of Cæsar's wife—not only without spot, but without suspicion.

There was, therefore, no alternative—the matter required to be probed to the bottom, and it was fortunate that the equitable determination was arrived at by the Trustees, to abide by the decision of a professional jury. Such a decision has now been awarded, and in the conclusions of that award we rejoice to learn that all parties are inclined to acquiesce. "No imputation rests on the moral character of Dr. Baird,"—unless, perhaps, by an excess of refinement it be imputed to him, that he carries his thoughts too openly.

To the profession at large there will be a lesson in those proceedings—the imperative duty of caution will be inculcated, and whether in public or private practice it will be seen that the best policy will be to avoid all those questionable modes of action, that may give a handle to the machinations of the mischievous. We live in times when the worst construction may be put on proceedings of the most harmless nature, and when cunning vice may find many an opportunity of sating its spleen or its

revenge. In the case before us, the occasion of the whole trouble may be attributed to an over-zealous anxiety for the proper treatment of a patient, or at the worst to an unlucky curiosity to ascertain facts of a collateral medico-legal nature. Hence officiousness had its exercise: a mine of mischief was worked up to a degree painful to be considered: meddlers helped to make matters worse; and by an ill-directed *esprit de corps*, the self-appointed supporters of the dignity of the profession ceased not till the whole business assumed an alarming aspect. At this juncture the better genius of the friends of order prevailed: the verdict of a competent tribunal restored the harmony that was ajar; and we will now hope that the feelings which were bitterly excited in the course of this unpleasant scene of contention will gradually assume that tranquillity with which time and their own integrity can endow them.

IRISH COLLEGE OF SURGEONS.

WE anticipated that our remarks on the proceedings of our brethren in Dublin, as connected with the Irish Grand Jury Bill, would prove rather unpalatable. A Mr. JAMES RAWSON has written us an angry letter from Lichfield, and like most angry people has blinked the main question. Our object was to expose the illiberality, selfishness, and injustice of excluding from the Hospitals, Infirmaries, and Dispensaries, in Ireland, all surgeons who were members of the London or Edinburgh Colleges — all, in short, who had not passed in Dublin, and lodged at the minimum fifty guineas in bank for the use of the College. This we protested against, and contrasted with the system here, which admits all of equal education to equal privileges. But Mr. Rawson neglects the brunt of the argument, and fixes upon one collateral circumstance, namely, our statement — that to become a member of the Irish College the party must have been apprenticed in Ireland. This, Mr. Rawson says, is not the case, and we admit that he is *literally correct*; inas-

much as we ourselves stated in a former notice (vol. xi. p. 859), that the College grants an examination to no student who has not been apprenticed to one of their members, *or educated on a system still more objectionable*; and which we may now add, is such as almost to amount to exclusion, as we demonstrated in our first article on this subject, so far back as Dec. 26, 1829. When Mr. Rawson can make out any good defence of the measure which we have condemned, we shall be glad to publish it; but then he must grapple with the question as a whole, and not with one detached portion of it.

EVIDENCE OF MEDICAL PRACTITIONERS AT CORONERS' INQUESTS.

A FEW days ago Mr. Godrich, of Chelsea, was summoned before Mr. Stirling to give his evidence, which, however, he refused to do, unless he were paid.

This involves an important question as regards medical men, and one which is not altogether clear in point of law. A very eminent member of the long robe on being consulted not long since on this point, gave it as his opinion, that the Coroner could summon to attend his court any one whom he believed capable of giving any information as to how the deceased had come by his death; and that he could oblige the witness to speak as to mere matters of fact — on the same principle as any other individual may be compelled to state what he knows as to the mode of death — but that no professional man, and of course no surgeon, can be forced to give an *opinion* without remuneration. Now, if this be correct, the line of demarcation as to what a medical man may safely refuse to answer is very well settled; and as it is on professional or scientific points that our assistance is almost always required, so it would very rarely happen that the desired evidence could be obtained without entitling the medical practitioner to remuneration.

RE-APPEARANCE OF CHOLERA IN PARIS.

WE regret to announce that cholera has again broken out in Paris. On the 20th and 21st, within forty-eight hours, eighteen cases were brought to the Hôtel

Dieu, seven of which proved fatal within a few hours; being quite as many cases and as many deaths as took place at this great hospital within the same period at the onset of the epidemic of 1832. Of course it is impossible, in a disease so inscrutable, to predict what may be the fate of Paris on this occasion; but one thing is now clear—that it is quite visionary on the part of the European governments, and that of France among others, to attempt, by any rigour of quarantine, the exclusion of an evil that is already in the midst of them, with which every portion of the Continent is now imbued, and which requires but the aid of favouring circumstances to become developed. They might just as well issue their manifestoes against small-pox, scarlatina, or measles.

CHOLERA IN SPAIN.

CHOLERA rages in Seville, Cordova, Granada, and Malaga: it has also appeared in Estramadura, and cases which have been concealed are said to have occurred in Madrid. As yet its greatest ravages have been in Seville, where it seems first to have broken out, and where the lower classes of the people have suffered very severely. It is a curious fact, taken in conjunction with this information, that clean bills of health were last week refused to vessels proceeding to Spain from the port of London, lest they should carry the disease to the Peninsula.

ALDERSGATE-STREET DISPENSARY.

No accommodation has been come to between the committee and medical men. The former seem determined to make no overture, but on the contrary have been making the most strenuous efforts to obtain candidates for the six medical vacancies. None, however, have yet ventured to announce themselves, though some of the members of the Committee state that their canvass for Doctors has not been unsuccessful. As the matter now stands, it is a contest between the medical men and a set of busy meddling persons, chiefly tradesmen, who are desirous to shew in how light an estimation they hold a profession the members of which they have hitherto, perhaps, found but too ready to accept their ap-

pointments. We have been rather astonished to find that the Committee have got persons to do the duty *ad interim**, and we confess we do not see why they should not undertake it permanently on the same principle as they do so for a time. The feeling in favour of the step taken by the late medical officers is very general among the members of their own profession, and we subjoin a copy of certain resolutions which the practitioners at Sheffield have come to, declaratory of their sentiments on this occasion.

To the late Medical Officers of the Aldersgate-Street Dispensary, London.

GENTLEMEN,—At this interesting period in the state of our profession, and especially of the government of medical charities, we should be guilty of the most culpable apathy and indifference did we not hasten to express the high satisfaction with which we have viewed your conduct on a late occasion—did we not testify how completely our feelings and sentiments are in unison with your own—did we not publicly record our warmest admiration of that brilliant example of integrity and independence which you have exhibited to your medical brethren.

Whatever sacrifice of feeling or of interest has been made, you have the consolatory approval of upright consciences. You have acted consistently, and like honourable men. You have discharged an important duty both to medical practitioners and to society at large. You have nobly withstood a most disgraceful attempt to degrade your profession, and to convert an health-giving charity into an infected source of misery and wretchedness; and whilst you enjoy the praise of every virtuous and enlightened mind, it may perhaps prove a further gratification to know that your medical brethren in particular are fully alive to the moral force of your example, that they appreciate its worth, and are resolved its memory shall not die.

Gentlemen, we hail this example, the first practical inroad on a protracted and systematic abuse of medical charities, as the harbinger of a general and efficient reform in those charities; we hail it as the forerunner of an approaching day,

* Physicians—Dr. Yates and Dr. Whitsed: Surgeons—Mr. Dalrymple, Mr. Caswall, and Mr. Wyatt.

when the legislature shall rescue them from longer prostitution of their legitimate ends—a day, when the neglected objects of science, and the aims of general utility and benevolence, shall happily be united—when nor personal interest, nor gold, nor any other corrupt means whatever, shall give notoriety to the officer of an hospital or dispensary, but when talent and knowledge alone, approved by public competition, shall be the test of fitness for office in such institutions.

The folly which compelled your withdrawal from the charity you upheld, foresaw not the consequences about to follow. Its sordid calculations of gain did not reckon that, with the loss of your labours and skill, the very charity you served would cease to exist; for where shall be found the men reckless enough to succeed you? The very attempt would brand their characters with all that is low, degraded, and debased.

Accept, gentlemen, this tribute of our gratitude; we deeply feel the obligation under which you have laid the whole profession. Assuredly the members of that profession will not forget a lesson so disinterested and elevated as that which you have given for their instruction, signalized too, as it is, by names distinguished in the scientific and literary history of their country.

We remain, gentlemen,
With the greatest respect and admiration,

Corden Thompson, M.D., Physician to the Sheffield General Infirmary; Wilson Overend, Surgeon to the Sheffield General Infirmary; Henry Paul Harewood, M.D., Physician to the Sheffield General Dispensary; John Green; George Calvert Holland, M.D., Physician to the Sheffield General Infirmary; Henry Thomas, Surgeon to the Sheffield Public Dispensary; Geo. Turton; R. G. Holland; Thomas Reade; Henry Hardy; Charles Eadon; Joseph Law; Joseph Inghall; R. S. Taylor; John Carr; James Wild; G. Reddal; George William Clark; James Ray; Jas. F. Wright; Edward Thompson; Henry Boulton, F.L.S.; Edward Gillott; W. Lennard, M.D.; Knowlton Wilson; John Hall; Samuel Gregory; John Pearce Lewis; John Foster; John Turton; Joseph Riley; William Staniforth, Senior Surgeon to the Infirmary;

Wright Wilson; Henry Jackson, Junior Surgeon to the Sheffield General Infirmary; James Walker; R. Ernest, M.D., House Surgeon to the Sheffield General Infirmary; John Pearson Shaw; W. Favell; John Haxworth, Surgeon; Wm. Jackson; Francis Pearson.

Sheffield, Sept. 22, 1833.

Letter of the Dispensary Committee.

The Committee have just addressed an angry ill-written letter to the Governors, professing to be an answer to the preceding address from Sheffield, as well as to a recent letter of Dr. Clutterbuck in the *Times*, but leaving the main question as to the expediency of putting up the medical appointments for sale, unanswered, though not unassailed. They are evidently exceedingly annoyed, both by the resignation and the circumstances attending it. Speaking of the medical men, they say—

“And not content with their threat of resignation, *but* they must add to it an insult to the Committee, by stating, that to remain in office with them, was incompatible with utility to the Dispensary, a due regard for the dignity of the Medical profession, and a just respect for their own characters. Although *we* could, as members of that Committee, with feelings of DIGNITY equal to any of the Medical profession, and with equal respect for *their* own characters, repel with indignation the insinuations thrown out against the Committee, *we* will, in mercy to the dignity of the profession, so virtuously represented by the authors of the paragraph, refrain from doing so.”

ST. GEORGE'S HOSPITAL.

CLINICAL REMARKS

ON AMPUTATION, &c.

BY MR. CÆSAR HAWKINS.

CASE 1. *Ulceration of the Cartilages of the Knee-joint from Scrofula.*

CASE 2. *Ulceration of the Cartilages of the Knee-joint from Erysipelas.*

CASE 3. *Disease of the Femur, with Hæmorrhage.*

MR. HAWKINS began by observing that he had been obliged, as he expected, to amputate the thigh of a boy named Willis, whose case had been the subject of a former clinical lecture; and as there were two other

patients in the hospital for whom he had performed the same operation, he would take the opportunity of noticing some circumstances connected with the operation of amputation which had occurred in the progress of these cases.

You will observe (Mr. Hawkins continued) that I did not remove Willis's limb simply because there was an abscess in the knee-joint, with ulceration of the cartilages, because that may sometimes be cured; but because the condition of the joint was complicated with a good deal of disease in the thigh also. Ulceration of the cartilages will sometimes follow an injury of the joint, and an acute abscess may take place, of a formidable nature, indeed, but still of a healthy character; so that if the patient survive the severe constitutional disturbance that accompanies such a state, ankylosis may subsequently occur, and the limb may be preserved. In the smaller joints, the elbow or wrist, for instance, I have even several times known portions of cartilage and bone exfoliate, and yet a useful limb remain to the patient.

So also when ulceration of the cartilages takes place without injury, from morbid action of its own vessels, or from disease of the synovial membrane extending to the cartilages, a recovery may occasionally take place. A young woman called at my house the other day, with a very useful leg for every thing but kneeling, who was formerly under my care in the hospital with ulceration of the cartilages of the knee-joint, into which an opening had been formed by abscess in two different places. In some rare cases after ulceration of the cartilages, even some degree of motion is preserved; in which case cartilage is not regenerated, but a smooth bony surface, or hard kind of ivory deposit, supplies its place.

When ulceration of the cartilages takes place in consequence of disease in the bones composing a joint, ankylosis does not so frequently occur as when it arises from either of the other causes which have been mentioned; yet you will very frequently see diseased joints, arising from scrofulous action in the epiphyses of the long bones, get permanently well, although ulceration of the cartilages has taken place, and has caused numerous abscesses in and around the joint; the joint being, of course, more or less stiff. There is a girl now attending the hospital, however, as an outpatient, who has had this disease for several years in the elbow-joint. When I first saw her, the epiphysis of the humerus was apparently firmly ankylosed with the ulna, and there was a complete separation, with free motion between the epiphysis and the shaft of the humerus, with copious discharge of pus from several sinuses com-

municating with the diseased part, so that I thought the loss of the limb almost inevitable; but by attention to the general health, union has taken place by new bone between the separated pieces of the humerus, and she will preserve the arm in an useful state for many purposes, as the ankylosis has taken place in the bent position of the joint.

Of this latter nature, probably, was the origin of the disease of the knee-joint in John Johnson, æt. 24, admitted April 18th, 1833, with the following history. He fell from a ladder twelve years ago, bending his knee under him with great force, and from that time his knee has been weak and painful whenever he used it; and occasionally he has been laid up for a few days at a time, with increased pain and inflammation. Thirteen weeks ago great swelling took place around the joint, especially in the ham, yet, notwithstanding this, he continued his work, the limb being bandaged in flannel; and while thrashing, an abscess burst in the ham, and discharged two quarts of matter. After this he kept his bed, having very copious discharge continued; and about a month afterwards another abscess was opened by the surgeon, below the patella, on the outside of the leg, and a pint of pus evacuated, which was mixed with blood. At the time of his admission the whole joint was much swelled with fluid, and on the inner side a considerable projection of the inner condyle was felt, as if it was enlarged, or had a bony tumor upon it. This part was not painful, but on the outside there was a good deal of pain and tenderness of the joint; and violent pain was produced by pressing the patella (which was somewhat displaced upon the outer condyle), against the bone below. Both the orifices of the abscesses allowed the probe to pass to a great depth; that in the ham towards, and probably into the knee-joint, though no bone was felt; that on the outside of the leg allowed the probe to pass towards the joint, and dead bone was felt in the tibia, close to the joint of the fibula with the tibia.

From the history of the case, therefore, and the age at which the disease commenced, it was probable that there was scrofulous disease established in the bones of the knee-joint (part of the tibia being now dead), which had subsequently spread to the joint itself, the cartilages being in a state of ulceration, and the abscesses probably leading into the joint, so that amputation seemed necessary.

The pain and swelling were first diminished by once cupping the knee, with cold lotion and rest. The operation was further delayed, however, by an attack on the 22d of acute gangrenous inflammation

round the opening of the abscess in the front of the leg, with great pain, and extensive dark redness of the parts around, there being almost complete stagnation of the blood in all the superficial veins of the leg and thigh. There was at the same time a good deal of constitutional disturbance, the pulse being 120, and the countenance expressing great anxiety. For this an effervescing draught, with carbonate of ammonia, and twenty minims of laudanum, were given every four hours, and a cold Goulard poultice applied.

23d.—The next day the gangrene had apparently stopped; he had had a good night, with little pain, and the pulse was only 90, and quiet.

The portion of skin and cellular membrane which were destroyed in this short time was nearly as extensive as the palm of the hand; but all the dark appearance of the surrounding parts, and of the veins of the limb, was gone. His mixture was continued, and three ounces of wine given him, which the next day was increased to six.

27th.—The large slough had come away, and a healthy ulcer exposed. Draught continued every six hours, with five minims only of laudanum.

30th.—The wine and some of the extra diet were omitted.

On the 2d of May his health was sufficiently re-established for the operation, and I accordingly amputated the thigh in the usual way. The cartilages of the joint, which you may see, were extensively ulcerated; the dead bone which was exposed was found to be loose in the head of the tibia, in the joint; and both the abscesses communicated with the interior of this cavity.

In Johnson's case the amputation was performed entirely above the diseased parts, or at least there was nothing but a little softening of the bone from disuse, with a corresponding laxity of union between the bone and its periosteum, which makes exfoliation after the operation a little more likely, but does not influence the mode of operation. But in the other two cases there was something more.

In Chandler, whose case we considered in the last lecture, the bone was almost double its natural size at the point where it was sawn across; yet you see that the inflammation of the bone has not in the least interfered with the success of the operation; no bone has exfoliated, and the stump is now nearly well. There was also in his case some condensation of the muscles from inflammation, which is a circumstance that will give you trouble in many operations; for the vessels in such cases cannot retract nor contract, and a vast number generally require the ligature;

and when you apply the silk, you find that the vessels have become quite brittle; the same vessel often requires to be tied several times before it is secure; and frequently you are obliged, instead of the tenaculum, to use a hook or a needle, and to enclose a little of the surrounding substances with the artery. Some gentlemen may recollect how much trouble was given by this state in the patient whose arm Mr. Brodie amputated not long since at the shoulder-joint.

In the operation in Willis's case, the state of the part was peculiar. The abscess around the femur extended up nearly to the trochanters, and it seemed probable, from the quantity of new bone which had formed around the necrosed part of the shaft, that dead bone reached up nearly as far; so that unless the amputation was performed very high up, which would render the operation considerably more dangerous, and would make the use of a wooden leg more difficult, from the shortness of the stump, I should have to divide a large abscess, and a mass of new bone, with inflamed soft parts, around a large piece of dead bone. The preservation of as much of the limb as could be kept with safety seemed of so much consequence, that the cutting across the vascular and inflamed part of the new bone and periosteum seemed, for the same reasons as in Chandler's case, to present no reason against removing the limb low down.

With regard to the dead bone, as a considerable time had now elapsed since the commencement of the disease, it seemed not improbable that it might be sufficiently loose to allow me, after having sawn across it, to extract what was dead from the end of the stump at the time of the operation; or else, if it was not then separated from the bone, that it would come away with facility at some future time. You will see by the preparation, that I was agreeably disappointed as to the extent to which the whole circumference of the bone was dead; it was so near the epiphysis, but at the part where it was sawn across, not above a third of the circumference was actually dead, which is hard and white, and firmly locked in by the old bone which remains alive, with the addition of a considerable quantity of new bone around it. You may see in the longitudinal section of the bone, which has been made, the very curious circumstance of some living cancellous structure inclosing a small abscess, which is almost entirely surrounded by the original ring of the femur, which has died. This is a fact which has been sometimes observed in experiments on animals, but which is not often seen in the human subject, in whom the separation or death of the periosteum is almost always followed

by the destruction of the membrane of the cancellous structure also. The appearance of the end of the bone will, of course, shew you what is the state of the bone at the end of the stump. I could not extract the dead part, though it does not probably reach very high; and it must be left to be partly absorbed, or to exfoliate, at some future time*.

In the next place, with regard to the abscess, it is very troublesome to cut across one in an amputation; but as this reached on one side of the bone to the trochanter minor, it seemed better to do so than to perform the operation so high up; but then such a method should, of course, lead to an entirely different mode of dressing after the operation. Union by the first intention does not very often occur after amputation; still it will do so occasionally; and it is therefore right to attempt to produce it when nothing forbids it. In Johnson the whole stump united by the first intention, and great part would probably have continued united, had it not been for the occurrence of erysipelas. In Chandler the number of ligatures interfered with complete union, and I brought them, therefore, all out at the centre of the wound, so that only the two extremities of the wound were allowed to unite; still a good deal was thus gained. In Willis, however, more was required, and I introduced a piece of blue lint (lint dipped in a solution of sulphate of copper) into the whole length of the abscess, by which the interior has been made to slough partially, and the centre of the wound has been prevented from uniting. In cases of this kind, then, where no union is at all probable, you can often introduce a piece of oiled lint, in order that matter may not be confined by the union of the edges of the skin; still even in these cases there is no necessity to cram the wound with lint in the continental style, since the union of half or a third of the wound at the two ends of the incision is of great use.

Again, in common cases, the wound should be left undisturbed for several days; as in Johnson, in whom the plaister was not taken away altogether for a full week, while in Willis I withdrew the lint on the second day; and you may see, in the few days that have elapsed since the operation, that the discharge has become quite healthy, and the cavity of the abscess is already contracting, from the free

exit afforded to the matter, and the new action produced by the stimulant application, while the two ends have firmly united.

Another point of great importance in the treatment of amputation, is the constitutional treatment of the patient after the operation. Where it is performed after an accident, it is often of great service to take away a small quantity of blood in the evening, or the next day, and to keep the patient strictly on low diet for several days; the fever which follows the operation being inflammatory: but where amputation is performed in consequence of disease, the case is wholly different. In Willis there had been much suffering, with hectic fever, previous to the operation; the cause of which being removed by it, he slept better the night after the operation than he had done for some time previously; but having been reduced by long continued disease, he did not require to be treated on the antiphlogistic plan. The only difference that I made in his treatment, before and after the operation, was to discontinue the wine that he had previously taken, but he was still allowed his porter, and fish or meat, with an opiate, to which he was now accustomed, and without which, though no longer kept awake by pain, he could not procure sleep. His tongue continued moist and clean, and, three days after the operation, instead of having fever of an inflammatory kind, there was a sensation of rigor, with a feeble pulse, and blueness of the lips, that induced me to order him again some wine and beef-tea, which restored him the next day to a more comfortable state.

In Johnson, also, the antiphlogistic plan very soon required to be changed for a better diet, and in a few days more for wine and brandy, and other stimulants, to prevent his sinking from exhaustion. He had a good deal of irritation previous to the operation, from the acute gangrene, which I have before mentioned; and a week after the operation was attacked with severe bilious vomiting, followed by erysipelas, which have drawn largely upon the strength of his system. This bilious erysipelas, as Dessault calls it, very quickly exhausts the patient, from the excess of vomiting, and the form which it assumes indicates the debility of the system. You never see erysipelas of the pale colour, and erratic form, which it assumed in Johnson, without being assured that the patient requires a good deal of support. Beginning on the stump, there is now no part of his body on which it has not successively appeared, except his remaining foot and one hand, and even on these it seems gradually creeping, after having lasted about three weeks. In Chandler, again, exhausted by

* Two months after the operation, a piece of bone about three inches in length was extracted, the stump having some time previously healed up, with the exception of a small sinus leading down to the dead bone, and the boy has since left the hospital, a vast quantity of new bone having formed since the operation, which has made the thigh almost twice as large as the sound one.

hæmorrhage, and by his attack of hospital gangrene, constant support has been required, besides the stimulants which were at first necessary, to prevent his sinking from weakness. It is obvious, then, that very different modes of constitutional treatment will be indicated after amputation, according to the state of each individual patient.

The next circumstance which I will allude to, is the occasional occurrence of retraction of the soft parts after amputation, producing protrusion of the bone, and an ill-formed conical stump. We are but too apt to attribute this, and other circumstances, to the fault of an operation, which may be the result of other causes; and Johnson's case will show you, perhaps, how this retraction takes place. There was amply sufficient soft parts to cover the bone, there was union by the first intention through the whole incision, and there would have been a very good stump but for the occurrence of erysipelas, with its accompanying constitutional disturbance. The consequence of this was an immediate absorption of the uniting medium, and retraction of the soft parts, with a foul and sloughy cavity. I recollect another case, in which, a few days after amputation of the thigh, a foul wound of the same kind was formed without erysipelas, the consequence of which was a similar contraction of the muscles. In a few days the constitutional disturbance ceased, and the wound cleaned, and the stump could again be readily covered without any force. About three weeks after this, secondary abscesses formed in the liver, and then, while the wound was quite healthy, and granulating well, the constitutional disturbance caused by the internal suppuration, caused retraction of the stump a second time, which again ceased before his abscess in the liver carried him off. You will easily understand, therefore, why retraction of the soft parts is more frequent when amputation has been performed for disease, than when it is done in consequence of accident; the irritation, or hectic, in the former case, tending to the production of this occurrence, which a person in a state of health avoids, though the operation be equally well performed, and there is exactly the same proportion of the integuments and other soft parts.

Now if retraction does take place, it is no use whatever to draw the integuments forcibly forward in order to bring the surfaces together: wait till the state of the system alters, and you have got rid of the irritation which produced the retraction, and then you will probably be able to close the wound again as well as at first. This was nearly the case you saw in

Johnson in a few days, even although the erysipelas continued in other parts of the body for so long a time. In this particular case, however, although a pretty good stump might ultimately have been formed, yet it could not have been done very easily, because the erysipelas had caused some thickening and condensation of the muscles and cellular tissue, and had produced also a little sloughing of the skin at one part of the wound. This was readily stopped indeed by chlorine and tincture of benzoin; but still I thought it better to hasten the filling up of the wound, and to ensure a still better stump by removing about an inch of the end of the bone, and the rather because a little portion of one side of the bone would ultimately exfoliate. This little operation could be done at this period without any difficulty whatever, the granulations upon the bone (which were very exuberant, and formed a considerable projection from the cancellous structure,) being just cut through, and the end of the bone sawn off. The stump was still at that time foul; but under our green dressing and other applications is now, healing fast. (Johnson has, in fact, as well as the other two patients, since left the hospital with a very good stump.)

The last occurrence which I will detain you by alluding to is the occasional exfoliation of the end of the bone in the stump, which will take place, no doubt, sometimes when there is nothing wrong in the operation, but which may, to a certain extent, be prevented by attending to these circumstances. When a person has suffered from long illness, or when the bone which is to be cut across has been inflamed, the periosteum becomes less closely attached to the bone, and during the operation it is liable to be torn away from its extremity. Thus, I rather expected a little exfoliation of bone from observing this fact in Johnson at the time of the operation, as there was some difficulty in securing all the vessels, and there was a good deal of spasmodic action of the muscles. In Chandler, also, a little portion of bone was exposed for the same reason, but the bone being more vascular — being, in fact, solid throughout in consequence of inflammation, no part appeared to die from the exposure. Another cause, I am inclined to think, of exfoliation after amputation is the too rapid motion of the saw, which is itself sufficient to excite inflammation. Certain it is, at all events, that from some cause or other the death and exfoliation of a small ring of bone is not uncommon, and now and then of a still larger piece. I have seen, for instance, a piece of bone of several inches which had thus exfoliated after the operation, though more commonly it is only a small ring of the outer surface

from the extremity of the bone. When a piece is thus felt exposed and dead, it should not in the least alter your treatment of the case: let the stump heal as far as it will: a little sinus will remain for a time, at the bottom of which the dead bone is felt, or a projecting mass of fungous granulation will make it appear likely that such a portion exists, though you may not be able to feel it, and the exfoliation will come away at some future period, or the dead piece will be absorbed; but in either case it seldom gives much trouble.

GLASGOW ROYAL INFIRMARY.

ON THE MORBID ENLARGEMENT OF THE CLITORIS AND NYMPHÆ.

I SHALL not now enter into any details regarding the congenital deviations from the natural appearance and size which these parts occasionally exhibit, but shall content myself with shortly narrating such cases of morbid enlargement as have presented themselves to my notice, and have required surgical interference.

CASE 1.—*Chronic Enlargement of the Clitoris and Nymphæ—Amputation of the parts—Cure.*—Mrs. M., æt. 25, admitted January 21, 1832. The clitoris formed a large pendulous and pyriform tumor, the pedicle of which was as thick as the thumb, and could be traced, in its enlarged state, for more than an inch under the pubes. The nymphæ were also considerably elongated, thickened, and had a warty appearance; and they, as well as the clitoris, were covered by a thin, smooth, and pale-coloured cuticle. The disease began two and a half years ago, six months after she had a syphilitic sore on the right nymphæ, which healed under mercury.

The history, progress, and appearance of the tumors, were conclusive as to their non-malignancy; they were, therefore, amputated on the 23d. The nymphæ and clitoris were pulled out as far as possible from the pubes, the external labia held aside by an assistant, and the parts divided close to their base; during which she seemed to feel exquisite pain. Three vessels were tied, the wound was covered with lint, and a T bandage applied; the parts granulated, and soon cicatrized.

On making a section of the parts, it was found that, in place of their naturally loose and spongy texture, they were firm and compact, but not otherwise morbidly changed.

When the clitoris and nymphæ are so elongated as to project beyond the labia, their natural appearance is destroyed, their functional sensibility impaired, and they obtain a covering of thin opaque cuticle.

This change would lead to the belief, that at one time the affected parts had been in a state of ulceration, and that their peculiar appearance depended on recent cicatrization. This is, however, not always the case; for although these morbid enlargements are often affected with superficial ulceration, yet, in general, the change in the appearance and structure of their external covering is to be attributed to the exposure and irritation occasioned by their external position, and to the want of the moisture by which they were formerly lubricated. They thus become dry and smooth, and the fine mucous membrane which originally covered them loses its natural appearance, structure, and secreting power, and is converted into an opaque and insensible cuticle.

In the following case, from the long continuance of fluor albus, and inattention to cleanliness, excoriations took place; chronic inflammation of the nymphæ and clitoris was excited; these parts enlarged slowly, projected beyond the labia, and, after seven years' growth, they were found hanging down to near the middle of the thighs.

CASE 2.—*Enlarged Clitoris and Nymphæ successfully extirpated.*—Mrs. P., æt. 46: February 14, 1827. The clitoris, which had been slowly increasing in size for about seven years, was nearly eight inches long, and of a pyriform shape. The pedicle was soft, as thick as the wrist, and traversed by varicose veins, whilst the most depending part of the tumor was hard, nodulated, and fully the size of two fists. The nymphæ hung alongside the pedicle for two and a half inches: they were irregular on the surface, covered by a thin white cuticle, and had a fleshy feel. The inner surface of the labia was covered by small tubercles, each being about the size of a split pea, and seated immediately under the mucous membrane. On the 20th, the diseased parts were amputated; the hæmorrhage was profuse, but was arrested by the application of five ligatures; a catheter was introduced, and retained in the bladder for several days. When the wound began to granulate, the urine was daily drawn off; by which means, the healing of the parts was accelerated, and complete cicatrization effected in about three weeks. I have lately seen this woman, and ascertained that she is in good health, and has not had any threatening of a return of the disease.

The diseased parts were of a solid fibrous texture; and the nodules, which occasioned the irregularity on the lower part of the clitoris, were situated immediately under the investing integument, and seemed to be in some measure distinct from the general tumor.

The clitoris of the female, as well as the penis of the male, may be affected with cancer. When the crura are enlarged, indurated, irregular, and painful, we may rest assured that the disease is beyond the reach of the knife; especially when the pendulous part of the tumor exhibits the characters of carcinoma. I was present, several years ago, at an operation for the removal of a cancerous clitoris: in this case, the nymphæ were not affected. The patient was secured as for the operation of lithotomy, and an attempt made to remove the diseased crura. After a painful and protracted dissection, during which the patient lost about a pound of blood, it was found impossible to remove all the affected parts. In a few weeks, a small fungous tumor began to project immediately above the meatus urinarius: it gradually enlarged; occasioned acute pain; bled profusely; and ultimately produced death. We ought to recollect, however, that, in a simple, benign enlargement of the clitoris, the crura may also be affected; but that this ought not to militate against the amputation of the diseased parts; for if the crura be divided, and allowed to remain, they will soon shrink and disappear*.

THE LATE DR. ALDERSON, OF HULL.

An admirably-executed statue of this lamented physician has been set up in front of the Infirmary, at Hull. It is said to be one of Westmacott's finest performances. On uncovering the statue—a ceremonial which took place on the 16th instant, being the fourth anniversary of the Doctor's death—several speeches were pronounced by way of *éloge* on the deceased, and expressive of the satisfaction of the subscribers in having contributed to the erection of so splendid and lasting a testimonial.

PROFESSOR SONNERBERG.

(From a Correspondent.)

PROFESSOR SONNERBERG, of Lund University, who has passed the summer in London, with the view of observing the medical institutions in this metropolis, and English literature with regard to the medical sciences, returned to Sweden on the 17th inst. *via* Hamburg, after a visit to Oxford.

LITERARY INTELLIGENCE.

In the press, *Surgical Essays*, the result of Clinical Observations made at Guy's Hospital. By Bransby B. Cooper, F.R.S. Surgeon of, and Lecturer on Anatomy at, Guy's Hospital.

In the press, *the Anatomy of the Human*

Eye, being an account of the History, Progress, and present State of knowledge of the Organ of Vision in Man. By John Dalrymple, Assistant Surgeon to the Ophthalmic Infirmary.

CHARLES HENRY ADAMS.

BOOKS RECEIVED FOR REVIEW.

Ueber die Transfusion des Blutes und die Infusion der Arzneien; von J. F. Dieffenbach, u. s. w. Berlin 1833.

A Compendious History of the Small-Pox, &c. By Henry George, Esq.

Outlines of Botany. By Prof. Burnett, of King's College.

An Essay on Inflammation and its Proximate Cause. By Philip L. Phillips, M.D.

A New Exposition of the Functions of the Nerves. By James W. Earle, Esq.

NOTICE.

"Scarificator" should give his name when he pretends to vouch for facts.

ERRATUM.—Page 827, col. 2, and p. 828, c. 2, for "figure," read "face."

W. WILSON, Printer, 57, Skinner-Street, London.

* Macfarlane's Hospital Reports.

INDEX to VOL. XII.

(VOL. II. FOR THE SESSION 1832-33.)

A.

- ABDOMEN, Dr. Bright on the functions of the, and some of the diagnostic marks of its disease, 281, 312, 345, 378.
- Acephalocysts, origin of, 214.
- Acid, hydrocyanic, Mr. Phillips on the preparation of, 801.
- nitric, case of poisoning with, for which the operation of laryngotomy was performed, with the appearances on dissection, and remarks by Mr. Arnott, 219.
- nitro-stearic, Messrs. Brett and Bird on, 805.
- prussic, Mr. Laming on a new method for the preparation of, 640, 837.
- chloric, Dr. Black on, 865.
- Adams, Mr. report of an operation performed by, at the London Hospital, for the excision of a large portion of the lower jaw, 159.
- Affaire Ramus, case of poisoning and murder, 259.
- Air, two cases of accidents from admission of, into the veins during surgical operations, 269.
- Air-cells, Dr. Elliotson on hæmorrhage from the, 136.
- Air-passages, Dr. Elliotson on hæmorrhage from the, 135.
- Alcock, Mr. notice of the death of, 720.
- Aldersgate-street Dispensary, notice of the proposed alteration at, with regard to elections, 475; report of the meeting at—resignation of his Royal Highness the Duke of Sussex (president) and of all the medical officers, 809.
- — — — — remarks on the points at issue between the governors of the, and the late medical officers, 844; vote of thanks to the latter, by the practitioners of Sheffield, 873.
- Aldis, Dr. on medical nomenclature, 676.
- Alison, Dr. of Edinburgh, remarks by, on the claims of Edinburgh physicians, 387.
- Allen, Mr. on the use of the bandage in parturition, 148.
- Amaurosis, M. Sanson on, 50, 62.
- Amputation, spontaneous, of the leg, 848.
- — — — — clinical remarks on, by Mr. Cæsar Hawkins, 875.
- Anatomy, tax on, Maxilla on the injustice of, towards the medical profession, 117.
- — — — — memorial to Lord Melbourne respecting the, 205.
- — — — — Act, the expenses of carrying its provisions into effect to be defrayed by the medical profession in the shape of a stamp duty, 89.
- — — — — and physiology, notice of a cyclopædia of, preparing for publication, 656.
- Anæsthesia and facial palsy, clinical lecture on, by Dr. Watson, 558.
- Analysis, chemical, by Messrs. Brett and Bird, of the serum and urine in anasarca, 567; of the fluid of a hydrocele, 764.
- Anasarca, serum and urine in, chemical analysis of, by Messrs. Brett and Bird, 567.
- Aneurism and heart, M. Dupuytren on the application of a ligature between the, 823.
- Aneurisms, M. Dupuytren on those which complicate fractures and wounds from fire-arms, and on their treatment by Anel's method, 859.
- Angina pectoris, Dr. Elliotson on, 408.
- Animalcule in the eye, Mr. Mackenzie on, with an account of a case in which a living cysticercus was detected in the anterior chamber, 111.
- Animals, diseased, M. Huzard's report on the exposing for sale the flesh of, 710.
- Annales d'hygiène publique et de médecine légale, critical analysis of the, 257, 741.
- Antimony, tartarized, on the treatment of inflammation of the lungs by large doses of, 191.
- Anus, artificial, Mr. Benington on a case of, successfully treated, 496.
- Anus, cases of prolapsus of the, cured by Mr. Hey's operation, 846.
- Aorta, aneurism of the, Dr. Elliotson on, 410.
- Mr. Humpage on a case of rupture of the, into the pericardium, 531.

- Aphthæ, Dr. Elliotson on the treatment of, 36.
- Aphonia, Dr. Elliotson on, 42.
- Apocynum cannabinum, Dr. Black on the, and its medicinal properties, 863.
- Apothecaries' Act, editorial observations on the contemplated change in the, 182; proposed remedy for defects in the, 209; suggested improvements in the, by Maxilla Inferior, 209, 255, 295; appeal to the profession respecting the proposed alteration in the, 253; on certain imperfections in the act of 1815, 254; suggested amendments of the, by Amicus, 324; resolutions on the subject of, passed at a meeting of the "Associated General Practitioners," 367; Maxilla Inferior on certain imperfections in the act of 1815, 359; remarks on the apprenticeship clause in the, 467.
- Apothecaries, Bill for better regulating the practice of, throughout England and Wales, 330; the amended, editorial observations on, 594; notice of the postponement of the, 364.
- the Scotch, petitions against, from Macclesfield, 361; from Wakefield, 398; from Bradford, 399; from Hull, *ib.*; from Birmingham, *ib.*; from the president and fellows of the King and Queen's College of Physicians in Ireland, 509; from Bath, 510; notice of the withdrawal of the, 475; extracts from the votes of the House of Commons respecting, 507.
- memorial of the Society of, to Lord Melbourne, 218; defence of the Company, in reply to Maxilla Inferior, 389.
- reform—remarks on Maxilla Inferior, by Molaris, 324.
- must examine M.D.'s, 466.
- Apprenticeship system, remarks on the, 429.
- Arm and fore-arm, Mr. Grantbam on a new form of splints for the, 532.
- Arnott, Mr. on a case of œsophagotomy, 28; on diseases of the eye, 95.
- Arrowsmith, Dr. on self-supporting dispensaries, with an account of that established at Coventry, 426.
- Arsenic, Mr. Mackenzie on the utility of, in choroiditis, 18.
- on the presence of, in the material of test tubes, 400.
- account of the preparations of, employed by M. Dupuytren in the treatment of malignant ulcers, 512.
- Arteries, M. Dupuytren on the ligature of, 823, 857.
- Artery, subclavian, ligature of the, performed with success, for a false consecutive aneurism of the axillary artery, 825.
- axillary, ligature of the, for aneurism of the subclavian, 857.
- Articulation, scapulo-humeral, M. Dupuytren on a case of caries of the, 622.
- Ascites, Dr. Elliotson on, 452.
- Ashburner, Dr. on the medicinal virtues of the *smilax aspera*, 350.
- on the teeth as a source of health or disease, 425.
- Asphyxia and death, M. Sardaillon on a case of, from exposure to the fumes of ignited charcoal, with remarks on the presumption of survivorship, 767.
- Association, provincial medical, the first volume of the transactions of, reviewed, 431.
- notice of the anniversary meeting of the, at Bristol, 591.
- Asthma, Dr. Elliotson on, 161.
- Atkinson, Mr. on a case of feline monstrosity, 294.

B.

- Babington, Dr. notice of the death of, 157.
- character of, by Dr. Bright, 264.
- 's, Dr. W. G. translation of Dr. Hecker on the Black Death in the Fourteenth Century, reviewed, 82.
- Badham, Professor, on the privileges, purposes, and prospects of medicine—a fragment from a valedictory lecture to the students of the University of Glasgow, 523.
- Dr. David, on the anticipation of modern discoveries in medicine in the works of ancient authors, 27.
- Dr. John, some account by, of the diseases usually treated in Montserrat, 238, 460.
- Baglivi, M. the opinions of, on the use of cantharides, 804.
- Baird, Dr. editorial observations on the alleged breach of professional delicacy by, 508, 870.
- Bandage, Mr. Allen on the use of the, in parturition, 148.
- Dr. Waller on the same, 201.
- Battley, Mr. observations by, on the *colchicum autumnale*, 462.
- Beings, organized, exceeding minuteness of, 480.
- Belinaye, Mr. on the medicinal virtues of *smilax aspera*, 353.
- Bell, Dr. on a simple mode of reducing a dislocation of the shoulder, 642.
- Bennington, Mr. on a case of artificial anus, successfully treated, 496.
- Berry, Mr. Grove, account by, of a labour case, with peculiar presentation, 46.
- Bile, Mr. Phillips on the secretion and uses of the, 49, 421.
- Black, Dr. on the influence of physical habits and employment on the size of different classes of men, 143.
- on the *apocynum cannabinum*, and its medicinal properties, 863; on chloric acid, 865.

- Blackmore, Dr. notes by, of the late Dr. Gregory's lectures on dyspepsia, hypochondriasis, and chlorosis, 732, 759.
- Bladder, Mr. Coulson on inflammation of the, with cases, 665.
- ulceration of the, with effusion of urine into the cavity of the abdomen, 816.
- Dr. Elliotson on the symptoms of stone in the, 817; general morbid anatomy of the, 820.
- account of a case in which a female catheter accidentally slipped into the, in drawing off the water, 837.
- Blood, coagulated, Dr. Henry Johnson on the consistence of, 797.
- transfusion of, Dr. Schneemann on a successful case of, 215.
- chemical analysis of the serum of, by Messrs. Brett and Bird, 494.
- Mr. Rees on the presence of urea in the, 676, 863.
- Messrs. Brett and Bird on the same, 703.
- Bloxam, Mr. on a case of dislocation of the hip, with fracture of the thigh, 702.
- Books, analyses and notices of:—Dr. Babington's translation of Dr. Hecker on the Black Death in the Fourteenth Century, 82; Mr. Tod on the anatomy and physiology of the organ of hearing, 150; Mr. Mayo's outlines of human physiology, 153; Mr. Rees's translation of Berzelius's analysis of inorganic bodies, 181; Ross's illustrations of the mechanism of parturition, 182; *Annales d'hygiène publique et de médecine légale*, 257; Dr. Granville's illustrations of abortion, &c. 259; *Cyclopædia of practical medicine*, part xvi. 325; Graves and Morries' *Hortus Medicus*, 326; Forster's dissector, *ib.*; Mr. Fletcher on the influence of the mind on the body, 392; transactions of the Provincial Medical Association, vol. i. 431; Hecker's *Johannis Cui Britannii de ephemeris Britannica liber*, 435; M. Velpeau's *embryologie*, &c. *ib.*; Mr. Russell on the testicles, 501; M. Velpeau's *Embryologie*, (2d notice,) 537; Main's *vegetable physiology*, 539; Mr. Madden on the infirmities of genius, 578; Dr. Caswall on the physiology of the organ of hearing, 615; Mr. Murray's manual of experiments, 617; Mr. Liddell on the illusions of the insane, 618; Raspail's *organic chemistry*, 644; Mr. Lawrence's treatise on the eye, 711; *Annales d'hygiène publique*, &c. Juillet, 741; *Cyclopædia of practical medicine*, part xvii. 743; Mr. Mayo on injuries and diseases of the rectum, 772.
- Bouillaud, M. on a new and singular variety of hermaphroditism, 50.
- clinical remarks by, on a case of intense peripneumony successfully treated, 542.
- Bourneau, M. clinical report by, of acute diseases treated at the hospital for children in Paris during the first three months of 1833—Diseases of the respiratory system, 157.
- Bowels, Mr. Eastcott on fatty discharges from the, 49.
- Brain, M. Montault on a remarkable case of hydatid cyst at the base of the, 80.
- Bread, M. Orfila on the detection of poison in, 257.
- Brett and Bird, Messrs. on the chemical constitution of urine in various diseases, 385.
- chemical analysis by, of the serum of the blood, 494.
- chemical analysis by, of the serum and urine in anasarca, 567.
- chemical analysis by, of the fluid of a hydrocele, 764.
- on urea, nitro-stearic acid, &c. in reply to Mr. G. O. Rees, 805.
- Bridges, Mr. Brunel's mode of constructing the arches of, 30.
- Bright, Dr. on the character of the late Dr. Babington, 264.
- on the functions of the abdomen, and some of the diagnostic marks of its disease, 231, 311, 345, 378.
- Bronchocele, Dr. Elliotson on, 1; its etymology, *ib.*; symptoms of, *ib.*; females most liable to it, *ib.*; period at which it usually commences, *ib.*; a frequent accompaniment of cretinism, 2; liability of brutes to, *ib.*; causes, *ib.*; treatment, 4.
- Bronchitis, Dr. Elliotson on, 70, 97; chronic, 98.
- Brockedon, Mr. on the uses of caoutchouc, and more especially its application to the manufacture of elastic web, 479.
- Brown, Mr. T. on a severe case of low fever, 105.
- on the insecurity of vaccination, 317.
- on the treatment of burns, 603.
- Brunel's (Mr.) mode of constructing the arches of bridges, 30.
- Brush, anodyne metallic or galvanic, for the cure of neuralgic affections, M. Hildenbrand's description of, 125.
- Bulman's, Mr. cases of hay fever, 165.
- Bulimia, congenital, extraordinary case of, 573.
- Burns, Mr. Brown on the treatment of, 602.
- Burials, weekly accounts of, 32, 64, 96, 128, 224, 272, 304, 336, 368, 400, 448, 480, 512, 544, 592, 624, 656, 688, 720, 752, 784, 816, 848, 880.
- Bury, Mr. on the contagiousness of erysipelas, 553; reply of, to Mr. Ellin's observations on, 738.

C.

- Callus, M. Dupuytren on the formation of, and the mode of remedying it when diseased or deformed, 332.
- Calvert, Dr. on dispensary associations, 577.
- Calamine, Mr. George on the use of, in confluent small-pox, 671.
- Calculi, the occasional presence of, in the stomach, noticed by Dr. Elliotson, 546.
- urinary, Dr. Elliotson on, 757.
- Cantharides, Dr. Hastings on poisoning by, 431.
- Baglivi's opinion of, 804.
- Caoutchouc, Mr. Brockedon on the uses of, and more especially its application to the manufacture of the elastic web, 479.
- Capsules, renal, Dr. Elliotson on disease of the, 725.
- Carbuncle, Mr. Ewen on a complicated case of, 251.
- Carditis, Dr. Elliotson on, 375.
- Caries, M. Dupuytren on a case of, of the scapulo-humeral articulation, 622.
- Cartmael, Mr. on recent improvements in the manufacture of salt, 29.
- Carriek, Dr. extract from the address of, at the meeting of the Provincial Association at Bristol, 621.
- Cassis, M. Vidal de, on a case in which he extracted a pin from the urethra, by the *tour de maître*, 249.
- Caswall, Dr. on the physiology of the organ of hearing, reviewed, 615.
- Catarrh, Dr. Elliotson on, 68.
- Catheter, case in which a, accidentally slipped into the bladder, in drawing off the water, 837.
- Chatto, Mr. on the uncertainty of the duration of labour, 801.
- Charities, medical, and self-supporting dispensaries, editorial observations on, 714.
- Chemistry, organic, M. Raspail's system of, reviewed, 644.
- Chevalier, Mr. on vaccination in hooping-cough, 321.
- Chevreur, M. on a particular class of muscular movements, 831.
- Chipman, Mr. on an improved truss, 835.
- Chlorine, on the internal use of, in nervous fever, 214.
- Choroiditis, Mr. Mackenzie on the utility of arsenic in, 18.
- Cholera, epidemic, Dr. Elliotson on the, 625.
- in Portugal, notice respecting, 123; queries respecting, 513; malignant, notice of the reappearance of cases of, in the metropolis, 475; Dr. Jameson's reply to three queries respecting, 614; Mr. Coy's reply to the same, 639; notice of the government arrangements respecting, 650; progress of, 680, 719; the new prevention act, *ib.*; state of, in the metropolis, 747; notice of the decrease of, 777; English, Dr. Elliotson on, 600; Mr. Rumsey on the motion of the limbs and increased temperature after, 836; state of the metropolis with regard to, 843.
- Circulation, placental, Mr. Marson on the the, 637.
- Clendinning, Dr. on the present state of toxicology, 440.
- Clitoris and nymphæ, Dr. Macfarlane on morbid enlargement of the, 879.
- College of physicians, papers read at the— Dr. D. Badham on the anticipation of modern discoveries in medicine in the works of ancient authors, 27; Sir Henry Hallford on the deaths of some illustrious persons of antiquity, 301; Dr. Clendinning on the present state of toxicology, 440.
- Colleges of physicians and surgeons, and society of apothecaries, parliamentary order regarding, 448.
- Colchicum autumnale, Mr. Battley's observations on, 462.
- Colic, Dr. Elliotson on, 549.
- Collier, Mr. on a case of enlargement of the tongue, 641.
- on a case of rupture of the duodenum, 766.
- Colon, case in which crystals were found on the surface of the, 214.
- Commission de lunatico, extracts from the professional evidence in the case of Lord Kingston, 621.
- Concours system, editorial observations on the working of the, 153.
- notice of a public (?) meeting in favour of the, 182.
- decorous doings of the, 263.
- at Paris, notice of the appointment of M. Rostan to the chair of clinique interne, 512.
- Conduction, electrical, Dr. Faraday on a new law of, 479.
- Concretions, gastro-intestinal, Dr. Elliotson on, 597.
- Corneitis, scrophulous, of both eyes, 95.
- Cornea, specks on the, M. Dupuytren on the treatment of, 478.
- Coroners' inquests, propriety of remunerating medical men for their attendance on, 150.
- editorial observations on the evidence of medical practitioners at, 874.
- Corporations, medical, and the apothecaries' bill, editorial article on the subject of the, 437.
- Cough, spasmodic and nervous, Dr. Elliotson on, 196.
- Coulson, Mr. on inflammation of the bladder, 665.
- Cove, Dr. on *Smilax aspera*, 501.
- Cox, Dr. Travers, on a case of hydrophobia, 835.
- Crane, Dr. on a case of gangrene of the lungs, successfully treated, 322.

Crampton, Dr. on the pathology of dislocation of the shoulder-joint, 242.
 Crosse, Mr. of Norwich, notice of the presentation of a piece of a piece of plate to, by his pupils, 845.
 Croup, Dr. Elliotson on, 65.
 Cuvier, Baron, notice of the erection of a bust in the Institute at Paris, to the memory of, 544.
 Cyanosis, Mr. Spackman on a case of, with an account of the morbid appearances, 737.
 Cyclops, foetal, case of, 752.
 Cyst, hydatid, at the base of the brain, M. Montault on a remarkable case of, 80.
 Cystitis, Dr. Elliotson on, 819.
 Cystorrhœa, Dr. Elliotson on, 819.

D.

Darwall, Dr. announcement of the death of, 681; biographical sketch of, 778.
 Deaf and dumb, statistics of the, 263.
 Deaths, a registry of the causes of, suggested by Dr. Gregory, 19.
 Degrees, medical, editorial observations on the expediency of conferring them in London, 504, 539.
 Delane, Mr. on a case of traumatic tetanus, successfully treated with carbonate of iron, 799.
 Desgenettes, M. notice of the sudden attack of, with hemiplegia, while lecturing, 192.
 Diarrhœa, Dr. MacLachlan on, 42.
 ——— Dr. Elliotson on, 593.
 Diabetes, Dr. Elliotson on, 726.
 Dilatation of the heart, Dr. Elliotson on, 377, 401.
 Discharges, fatty, from the bowels, Mr. Eastcott on, 49.
 Diseases, acute, M. Bourneau's clinical report of, treated at the hospital for children in Paris during the first three months of 1833, 157.
 Dispensary associations, Dr. Calvert on, 577.
 ——— Derby self-supporting, Mr. Jones on, with remarks on the system, 355.
 Dispensary, Sheffield public, protest of the governors of the, against the indiscriminate relief of applicants, 841.
 Dispensaries, self-supporting, editorial observations on, 581, 714.
 ——— Dr. Arrow-smith on, with an account of that established at Coventry, 426.
 Discoveries, modern, in medicine, Dr. Badham on the anticipation of, by ancient authors, 27.
 Dogmata, surgical, recapitulation of, by the professor of anatomy and surgery in the university of Dublin, 866.
 Drawing, Mr. Solly on the advantages of the art of, to the medical student, 802.

Dropsy, ovarian, Dr. Elliotson on, 454.
 ——— case related by Mr. Cæsar Hawkins, illustrative of the quantity of fluid secreted in, 458.
 Duchatelet, M. on the effect of dust and other supposed irritants on the lungs, 716.
 Duodenum, Mr. Collier on a case of rupture of the, 766.
 Dupuytren, M. clinical observations by:—on luxations of the humerus, 90; on a case of strangulation, 126; on grenouillette, or ranula, with an account of a new and successful mode of treatment, 139; on fibro-cellular tumors of the uterus, 184; on the formation of callus, and the mode of remedying it when diseased or deformed, 332; on fracture of the lower end of the radius, simulating dislocations of the wrist, 443; on gonorrhœal ophthalmia, 476; on the treatment of specks on the cornea, 478; on inflammation of the retina, *ib.*; on a case of caries of the scapulo-humeral articulation, 622; on hydrocele and its principal varieties, 682; on the treatment of goitre by setons, 719; on the ligature of the principal arteries, 823, 857.
 ——— account of the preparations of arsenic employed by, in the treatment of malignant ulcers, 512.
 Dust, M. Duchatelet on the effects of, and other supposed irritants, on the lungs, 710.
 Dysentery, practical remarks on, by Mr. Spence, 73, 113.
 ——— acute and chronic, Dr. Elliotson on, 553.
 Dyspepsia, hypochondriasis, and chlorosis, notes of lectures on, by the late Dr. Gregory, 732, 759.

E.

Ear-ache, Dr. Elliotson on, 57.
 Eastcott, Mr. on fatty discharge from the bowels, 49.
 Edinburgh surgeons, editorial observations on the claims of, to practise as apothecaries in England, 326.
 Ehrenberg, Professor, some account of the discoveries by, relative to the structure and functions of the infusoria, 601.
 Ellin, Dr. on the contagion of erysipelas, 633.
 Elliotson's, Dr. lectures on the theory and practice of medicine:—DISEASES OF THE THROAT—bronchocele, 1; its etymology, *ib.*; symptoms of, *ib.*; females most liable to, *ib.*; period at which it usually commences, *ib.*; frequently accompanies cretinism, 2; liability of brutes to, *ib.*; causes, *ib.*; treatment, 4; parotitis, 6; symptoms, *ib.*; treatment, *ib.*; tonsillitis, 33; attended with ulceration, 35; en-

- largement of the tonsils, *ib.*; foetid breath, arising from affections of the, 36; pustules on the tongue, lips, and cheeks, of infants, *ib.*; aphthæ, *ib.*; ear-ache, 37; pharyngitis, *ib.*; stricture of the œsophagus, 38; spasmodic constriction of the œsophagus, *ib.*; acute laryngitis, 39; chronic laryngitis, 41; aphonia, 42; tracheitis, or croup, 65; organic affections of the larynx and trachea, 67; catarrh, 68; influenza, 69. DISEASES OF THE CHEST—bronchitis, 76, 97; chronic bronchitis, 98; peripneumonia, 129; gangrene of the lungs, 133; hæmorrhage from the air-passages, 135; from the air-cells, 136; asthma, 161; catarrhus æstivus, or hay-fever, 164; whooping-cough, 193; spasmodic cough, 196; nervous cough, *ib.*; phthisis pulmonalis, 196, 225; acute pleuritis, 273; chronic pleuritis, 275; pneumato-thorax, 305; hydro pneumato-thorax, 306; tubercular disease of the pleura, 309. DISEASES OF THE HEART—acute pericarditis, 310; chronic pericarditis, 337; disease of the lining membrane of the heart, 338; diseases of the valves, 340; auscultatory signs, 369; sounds of the heart, 371; diseases of the substance of the heart, 375; carditis, *ib.*; hypertrophy, *ib.*; dilatation, 377, 401; aneurism of the heart, 405; induration and softening, 406; abscesses and ulceration, *ib.*; rupture of the heart, 407; of the valves, *ib.*; gangrene, *ib.*; ossification, *ib.*; ossification of the coronary arteries, 408; angina pectoris, *ib.*; other structural diseases, 409; cautions as to diagnosis, *ib.*; aneurism of the aorta, 410; acute peritonitis, 449; chronic peritonitis, 451; ascites, 452; ovarian dropsy, 454; tympanitis, 456; diseases of the pancreas, *ib.*; diseases of the spleen, 457; diseases of the liver, 481; hepatitis, *ib.*; jaundice, 486; gall-stones, 490; diseases of the gall-bladder, 492; morbid appearances in diseases of the stomach, 513; acute gastritis, 518; chronic gastritis, 520; ulceration, 521; rupture, 522; schirrus, 545; calculi, 546; hæmatemesis, *ib.*; acute enteritis, 548; colic, 549; paralysis after lead colic, 551; acute and chronic dysentery, 553; diarrhœa, 593; discharge of fatty matters from the alimentary canal and urinary organs, 596; gastro-intestinal concretions, 597; English cholera, 600; epidemic cholera, 625; disorders of the digestive organs, 630, 649; worms, 689; nephritis, 721; hæmaturia, 722; disease of the renal capsules, 725; functional diseases of the kidneys, *ib.*; ischuria, *ib.*; diabetes, 726; excess of urea in the urine, 733; discharge of fat, 754; urinary sediments, *ib.*; urinary calculi, 757; various kinds of, 785; treatment of, 787; lithiasis, 817; symptoms of stone in the bladder, *ib.*; cystitis, 819; cystorrhœa, *ib.*; general morbid anatomy of the bladder, 820; paralysis of the bladder, *ib.*; disease of the prostate, 821; gout, 821, 849; rheumatism, 851; concluding address, 855.
- Elliotson, Dr. on glanders in the human subject, 28.
- Embryologie, ou ovologie humaine, M. Velpeau's recent work on, reviewed, 537.
- England, Dr. on the necessity of a parliamentary inquiry into the state of the medical profession, 498.
- English and Scotch general practitioners, editorial observations upon the point at which they are at issue, 211.
- Enteritis, acute, Dr. Elliotson on, 548.
- Entozoa, Mr. Lawrence on the occurrence of, in the eyes of man and of other vertebralia, 711.
- Esquirol, M. on illusions in maniacs, 469.
- Epidemics, editorial article on the influence of, 119.
- Erysipelas, Dr. Ellin on the contagion of, 338.
- Mr. Bury on the contagiousness of, 553, 738.
- case of, of the head and face, with ulceration of the bladder, and effusion of urine into the cavity of the abdomen, 816.
- Erysipelas, Mr. Cæsar Hawkins on ulceration of the knee-joint from, 876.
- Ewen, Mr. on a complicated case of carbuncle, 251.
- Evidence, medical, notice by Dr. King of the influence of, on a question of criminal responsibility, 80.
- Extremities, Mr. Grantham on new forms of splints for the, 606.
- Eye, Mr. Mackenzie on diseases of the, 18, 110.
- M. Sanson's clinique on diseases of the, 30, 62.
- Mr. Arnott on diseases of the, 94.
- Mr. Middlemore on certain forms of disease of the, occurring in individuals who were suffering from, or had recently been attacked by, cholera, 492.
- Mr. Lawrence's treatise on diseases of the, reviewed, 711.
- F.
- Factory bill, notice of the postponement of the, until more evidence shall have been procured, 27.
- commission, correspondence with the secretary of state on the propriety of remunerating medical practitioners for information required of them, 365.
- Factories' regulation bill, notice of the defeat of, 541.
- Faraday, Dr. on the action of lime, carbonic acid, and water, on each other, 191.

Faraday, Dr. on a new law of electrical conduction, 479.
 Fasting, two extraordinary cases of, 571.
 Fat, Dr. Elliotson on the discharge of, from the alimentary canal and urinary organs, 596, 754.
 Fauces, posterior, source of hæmorrhage from ulcers of the, 510.
 Femur, necrosis of the, clinical remarks on, by Mr. Cæsar Hawkins, 747, 811.
 ——— Mr. Cæsar Hawkins on a case of disease of the, with hæmorrhage, 747.
 Fever, scarlet, Mr. Sandwith on the theory and treatment of, 28.
 ——— low, Mr. Brown on a severe case of, 106.
 ——— nervous, on the internal use of chlorine in, 214.

- Harveian oration, notice of, 440.
- Hastings, Dr. on poisoning by cantharides, 431.
- Hawkins, Mr. Cæsar, case related by, illustrative of the quantity of fluid secreted in ovarian dropsy, 458.
- clinical remarks by, on a rare form of disease of the knee-joint, 652.
- clinical remarks by, on necrosis of the femur—hæmorrhage—erysipelas—abscess in the knee-joint—amputation, 747, 811.
- clinical remarks by, on amputation, 875.
- Hay fever, Dr. Elliotson on, 164.
- Mr. Gordon's description of, 164; another description of, 165; Dr. Bulman's cases of, *ib.*; Mr. Poyser's cases, 166.
- Heath, Dr. on a new mode of applying friction, 465.
- Heart, Dr. Elliotson on disease of the lining membrane of the, 338; of the valves, 340; auscultatory signs, 369; sounds, 371; diseases of its substance, 375; carditis, *ib.*; hypertrophy, *ib.*; dilatation, 377, 401; aneurism, 405; induration and softening, 406; abscesses and ulceration, *ib.*; rupture, 407; of the valves, *ib.*; gangrene, *ib.*; ossification, *ib.*; of the coronary arteries, 408; angina pectoris, *ib.*; other structural diseases, 409; cautions as to diagnosis, *ib.*; aneurism of the aorta, 410.
- Hearing, Mr. Tod on the anatomy and physiology of the organ of, reviewed, 150.
- Dr. Caswall on the physiology of the organ of, reviewed, 615.
- Head and face, case of erysipelas of the, with ulceration of the bladder, and effusion of urine into the cavity of the abdomen, 816.
- Hecker's *Johannis Cui Britanni, &c.* reviewed, 535.
- Hepatitis, Dr. Elliotson on, 481.
- Hermaphroditism, account by M. Bouillaud of a new and singular variety of, 50.
- Hernia, thoracic, Mr. Morgan on a case of, 673.
- Hetting, Mr. on osteo-sarcoma of the jaw, 434.
- Hildenbrand's, M. description of his anodyne metallic or galvanic brush, for the cure of neuralgic affections, 124.
- Hingeston, Mr. on the late influenza, 198.
- Hip, Mr. Bloxam on a case of dislocation of the, with fracture of the thigh, 702.
- Hobson, Dr. on the employment of croton oil as an irritant, 497.
- Hodson, Mr. on a case of lithotomy, in which he extracted a large calculus, 387.
- Hooping-cough, Dr. Elliotson on, 193.
- Mr. Chevalier on the effects of vaccination in, 321.
- Mr. Greenhow on the treatment of, 384.
- Hudson, Mr. on a case of fracture of the jaw, 674.
- Hufeland, honours to, 624.
- Hughson, Mr. on the nature of the venous openings in the uterus, and on the priority of their discovery, 115.
- on the apertures in the uterine veins, 202.
- Humerus, clinical observations by M. Dupuytren on luxations of the, 90.
- case of dislocation of the, backwards, on the dorsum of the scapula, 478.
- Humpage, Mr. on a case of rupture of the aorta into the pericardium, 531.
- Huzard, M. report by, on the exposing for sale the flesh of animals which have died of various diseases, 710.
- Hydrophobia, Dr. Travers Cox on a case of, 835.
- Hydro-pneumato-thorax, Dr. Elliotson on, 306.
- Hydrocephalus, Dr. Traill on a case of, 434.
- Hydrocele, and its principal varieties, clinical observations on, by M. Dupuytren, 682.
- Messrs. Brett and Bird's analysis of the fluid of a, 764.
- Hypertrophy of the heart, Dr. Elliotson on, 375, 411.
- congenital, of the liver, case of, 804.

I.

- Iliac, external, M. Dupuytren on ligature of the, 826.
- Illusions in maniacs, M. Esquirol on, 469.
- Infirmeries (Ireland) bill, abstract of the, 475.
- Influenza, Dr. Elliotson on, 69.
- epidemic, notices respecting the, 62, 124, 156.
- the late, Mr. Hingeston on, 198.
- Dr. Rawlins on, and on sulphate of quinine as a remedy for, 252.
- Infusoria, account of Dr. Ehrenberg's discoveries relative to the structure and functions of the, 601.
- Inquest at Colchester, editor's opinion of the conduct of the parties engaged in the, 507.
- Insane, Mr. Liddell's observations on the illusions of the, reviewed, 618.
- Intoxication, excessive, cases of, 804.
- Irish grand jury bill, notice of the postponement of the, 396.
- Iron, carbonate of, Mr. Dehane on a case of traumatic tetanus successfully treated by, 799.

- Ischuria, Dr. Elliotson on, 725.
 Jacksonian prizes for the year 1834, the subjects proposed for, 651.
 Jameson, Dr. reply by, to three questions respecting cholera, 614.
 Jaw, lower, report of an operation performed by Mr. Adams, for the excision of a large portion of the, 159.
 ——— osteo-sarcomatous tumor of the, cured by operation, 590.
 ——— extraordinary case of extensive destruction of the, by a shell, with an account of the recovery of the patient, and a description of an ingenious contrivance for remedying the loss of parts, 705.
 — Mr. Hetling on osteo-sarcoma of the 434.
 — Mr. Hudson on a case of fracture of the, 674.
 — fractures of, description by Mr. Lonsdale of an instrument for the treatment of, 565.
 Jaundice, Dr. Elliotson on, 486.
 Johnson, Dr. Henry, on the consistence of coagulated blood, 797.
 Joints, Mr. Key on the ulcerative process in, 267.
 Jones, Mr. on the Derby self-supporting dispensary, with remarks on the system, 355.
 Jurisprudence, medical, Dr. Locock on a case of—question of time of birth, 636.
 ——— time of birth, tenancy by courtesy, remarks on, 677.

K.

- Key, Mr. on the ulcerative process in joints, 267.
 Kidneys, Dr. Elliotson on functional diseases of the, 725.
 King, Dr. notice by, of the influence of medical testimony on a question of criminal responsibility, 80.
 Knee-joint, Mr. Cæsar Hawkins on a rare form of disease of the, 652.
 ——— ulceration of the cartilages of the, from scrofula, 875; from erysipelas, 876.
 Knee, description by Mr. Grantham of an apparatus for fractures below the, 739.

L.

- Labour, account, by Mr. Grove Berry, of a peculiar presentation in a case of, 46.
 — Mr. Robertson on the advantages to be derived from the classification of cases of, 77.
 — difficult, Mr. Tyerman on a case of, followed by hysteritis, 704.

- Labour, Mr. Chatto on the uncertainty of the duration of, 801.
 Laming, Mr. on a new method of preparing medicinal prussic acid, 640, 837.
 Lancet, piracies of the, 439.
 Larynx and trachea, Dr. Elliotson on organic affections of the, 68.
 Laryngitis, acute, 39; chronic, 41.
 Latham, Dr. on the duration of fevers, 418.
 Lawrence's, Mr. treatise on diseases of the eye, reviewed, 711.
 Leading articles:—Norwich jury of matrons, 22; on the communication between the mother and the fœtus, 55; Edinburgh graduates, 86; influence of epidemics, 119; working of the Concours system, 153; contemplated change in the apothecaries' act, 182; English and Scotch general practitioners, 211; the Gower-street *Valetudinarium*, 260; things as they were before 1815, 297; Edinburgh surgeons and English apothecaries, 326; observations on a letter from the Rev.  xeroma conjunctivæ, 44.
 ——— account by, of a case in which a living cysticercus was detected in the inner chamber of the eye, 111.
 Main's, Mr. illustrations of vegetable physiology, reviewed, 539.
 Maniacs, M. Esquirol on illusions in, 469.
 Marson, Mr. on the placental circulation—Cæsarean operation, 637.
 Matrons, jury of, editorial observations on the verdict delivered by, in a recent case tried at Norwich, 24.
 ——— the late jury of, at Norwich, the opinion formed by, found to be incorrect, 585.
 Maxilla, paper by, on the injustice of imposing a tax on the medical profession, for defraying the charges of the anatomy act, 117.
 Mayo's, Mr. outlines of human physiology, reviewed, 153.
 ——— Professor, physiological observations by, 634.
 ——— Mr. observations on injuries and diseases of the rectum, reviewed, 772.
 Medicine, Dr. Badham on the anticipation of modern discoveries in, in the works of ancient authors, 27.
 ——— Birmingham school of, notice of the distribution of prizes at the, 400.
 ——— on the study of polite literature as connected with the practice of, 403.
 ——— Professor Badham on the privileges, purposes, and prospects of—a fragment from a valedictory lecture to the students of the University of Glasgow, 523.
 ——— on the value of scientific pursuits in connexion with the study of, 643.
 ——— practical, critical notice of Part 17 of the cyclopædia of, 743.
 Medico-Chirurgical Society, papers read at the:—Mr. Arnott on a case of œsophagotomy, 28; Dr. Elliotson on glanders in the human subject, *ib.*; Mr. Sandwith on the theory and treatment of scarlet fever, *ib.*; Dr. Lee on phlebotomy, 29; Mr. Key on the ulcerative process in joints, 267.
 Melanosis, Dr. Williams on a case of, 434.
 Mercury, Mr. George on the injurious effects of, in certain forms of disease, 569.
 Meteorological journal, 32, 64, 96, 126, 224, 272, 304, 336, 368, 400, 448, 480, 512, 544, 592, 624, 656, 688, 720, 752, 784, 816, 848, 880.
 Middlesex Hospital: cases, with remarks, by Mr. Arnott, 94, 126, 219, 366, 478, 510.
 Middlemore, Mr. on certain forms of disease of the eye, occurring in individuals who were suffering fever, or had recently been attacked by cholera, 492.
 Movements, respiratory, questions by Philalethes to Dr. Philip on the nature of the, 469.
 Montault, M. on a remarkable case of hydatid cyst at the base of the brain, 80.
 Monstrosity, feline, Mr. Atkinson's case of, 294.
 ——— canine, singular example of, 688.
 Montserrat, Dr. John Badham on some of the diseases usually treated in, 238, 460.
 Mordaxim, or cholera, of Java and Malabar, observations on the, 535.
 Morgan, Mr. on a case of thoracic hernia, 673.
 Morris, Mr. on the co existence of cow-pox and small-pox, 834.

Mouse, singular case in which one was swallowed alive, 544.

Movements, muscular, M. Chevreul on a particular class of, 831.

Murray, Dr. account by, of a case of tetanus, with remarks on the division of nerves as a method of cure, 15.

——— Mr. manual of experiments illustrative of chemical science, reviewed, 617.

N.

National vaccine board, defence of the, against the late objections of Dr. Brown, of Mussleburgh, 740.

Needle buried in a man's heart, 720.

Nephritis, Dr. Elliotson on, 721.

Nerves, Dr. Murray on the division of, as a method of curing tetanus, 15.

Nomenclature, medical, Dr. Aldis on, 676.

O.

Oesophagotomy, Mr. Arnott on a case of, 23.

Oesophagus, Dr. Elliotson on stricture of the, 38; spasmodic constriction of the, *ib.*

——— case of stricture of the, with scirrhus of the part, 366.

——— Dr. Hannay on an extraordinary dilatation (with hypertrophy?) of the thoracic portion of the, causing dysphagia, 769.

Oil, croton, Dr. Hobson on the employment of, as a counter-irritant, 497.

Ophthalmia, catarrho-rheumatic, cases of, with remarks by Mr. Arnott, 94.

——— gonorrhœal, Baron Dupuytren on, 476.

Opium, constituents of, 400.

Orfila, M. on the detection of poison in bread, 257.

Organs, digestive, Dr. Elliotson on disorders of the, 630, 649.

Os incus, Mr. Jones on the structure of the, 171.

Os hyoides, case of fracture of the, cured, 64.

Osteo-sarcoma of the jaw, Mr. Hetling on, 484.

P.

Paletta, M. biographical sketch of, 684.

Palsy, facial, and anæsthesia, Dr. Watson's clinical lecture on, 558.

Pancreas, Dr. Elliotson on diseases of the, 456.

Paris hospital reports, 126, 752.

Paralysis, Dr. Elliotson on the occurrence of, after lead colic, 551.

Parturition, Mr. Allen on the use of the bandage in, 148.

——— Dr. Waller on the use of the bandage in, 201.

Parotitis, Dr. Elliotson on, 6; symptoms and treatment of, *ib.*

Pericarditis, chronic, Dr. Elliotson on, 337.

Periostitis, case of, over the trochanter, with suppurating nodes on the head, 127.

Peripneumonia, Dr. Elliotson on, 129.

——— clinical remarks by M. Bouillaud on an intense case of, 542.

Peritonitis, acute, Dr. Elliotson on, 449; chronic, 451.

Pericarditis, acute, Dr. Elliotson on, 310.

Pericardium, Mr. Humpage on a case of rupture of the aorta into the, 531.

Pharyngitis, Dr. Elliotson on, 57.

Philip, Dr. A. P. W. on the nature of sleep, 695.

Phillips, Mr. on vascular tumors, 7.

——— on the secretion and uses of the bile, 49.

——— on the functions of the liver, and uses of the bile, 421.

——— the Jacksonian prize awarded to, for the best essay on the mode of union in simple and compound fractures, 124.

——— on the preparation of hydrocyanic acid, 801.

Philalethes, questions by, to Dr. Philip, on the nature of the respiratory movements, 469; answers to, by Criticus, 497.

Phlebolites, Dr. Lee's opinion of the nature of, 29.

Phrenology, new discoveries in the science of, 448.

Phthisis pulmonalis, Dr. Elliotson on, 196, 225.

Physicians, London, memorial of, praying for an inquiry into the state of the medical profession, 330.

——— college of, plan for a reform in the, 536.

——— defence of the, 542.

——— petition of the licentiates of the, editorial observations on the, 647.

——— statement of the finances of the, 688.

——— copy of the regulations or bye-laws under which the graduates of physic have been admitted as fellows of the, since the year 1771, 651.

Physician, extracts from the portfolio of a, practising in London—congenital hypertrophy of the liver, 804; Baglivi on cantharides, *ib.*; cases of excessive intoxication, *ib.*; influence of manner upon a physician's success, 805.

Physicians, Edinburgh, Dr. Alison on the claims of, 387.

Physician, influence of manner upon the success of a, 805.

Placenta, Dr. Hugh Ley on the structure of the, 287.

——— structure of the, account by Messrs. Stanley and Mayo of their examination of the Hunterian preparation in the College of Surgeons, 353.

——— Dr. Rigby on the structure of the, and the connexion between the foetal and the maternal vessels, 527.

Player, Mr. on a case of purpura hæmorrhagica, 608.

Pleura and lungs, the symptoms of inflammation of the, in a boy of 15, successfully combated by large doses of tartarized antimony, 158.

——— tubercular disease of the, Dr. Elliotson on, 309.

Pleuritis, acute, Dr. Elliotson on, 273.

Pneumato-thorax, Dr. Elliotson on, 305.

Poisoning, suspected, with a mineral acid, MM. Baruel and Orfila on a case of, with an account of the method adopted by these eminent chemists for examining some fluids in phials and in the human stomach, 742.

——— chemical examination of the contents of the stomach in a case of, 861.

Polypi, uterine, M. Dupuytren on the signs of disorganization in, 186; importance of ascertaining the form of, 189; structure of, *ib.*; frequency of, at different ages, 190; effects of marriage and celibacy, *ib.*; of fecundity and sterility, *ib.*; of the state of menstruation, 191.

Polity, medical, editorial observations on the attention of parliament to, 744.

Poyser's, Mr. cases of hay fever, 166

Practitioners, associated general, resolutions on the subject of the apothecaries' act, passed at a meeting of, 367.

——— general, Mr. Thomas, of Liverpool, on the legal claims of, 574.

Prevost, M. on double vision, 266.

Profession, medical, Dr. England on the necessity of a parliamentary inquiry into the state of the, 498.

——— Mr. Warburton's notice of motion for an inquiry into the present state of the, 507.

——— editorial observations on the attacks of the press on the, 678.

Prolapsus of the anus, cases of, cured by Mr. Hey's operation, 846.

Prostate, Dr. Elliotson on disease of the, 321.

Pupil, contracted, case of, with synchysis of right eye and atrophy of the left, 126.

Purpura hæmorrhagica, Mr. Player on a case of, 608.

Pursuits, scientific, on the value of, in connexion with the study of medicine, 612.

Pustules, Dr. Elliotson on the treatment of, when occurring on the tongue, lips, and cheeks of infants, 36.

Q.

Quetelet, M. on the weight of man at different ages, 741.

Quinine, sulphate of, its employment in the treatment of influenza recommended by Dr. Rawlins, 253.

R.

Radius, case of fracture of the, with displacement of the hand in consolidation, reduced on the twenty-fifth day, 336.

——— M. Dupuytren on fracture of the lower end of the, simulating dislocation of the wrist, 443.

Ranula, case of, of three years' standing, perfectly cured in fifteen days, 142; another case, in which the treatment was modified with advantage, *ib.*; example of the comparative merits of the old and new methods of treatment — complete success of the latter, *ib.*

Raspail, M. his system of organic chemistry, reviewed, 644.

Rawlins, Dr. on influenza, and on sulphate of quinine as a remedy for, 252.

Reciprocity, Irish system of, editorial observations on the, 472.

Rectum, Mr. Mayo's observations on injuries and diseases of the, reviewed, 772.

Rees's, Mr. translation of Berzelius's analysis of inorganic bodies, reviewed, 181.

——— Mr. G. O. reclamation by, to Messrs. Brett and Bird, on the process for the detection of urea, 765.

——— on the presence of urea in the blood, 676, 863.

Reform, medical, *Irish* specimen of, editorial observations on, 806.

Reform, medical, observations on, by Glasgowensis, 369.

Retina, inflammation of the, M. Dupuytren on the treatment of, 478.

Rheumatism, acute, account, by Mr. George, of a singular recovery from, 19.

Rheumatism, Dr. Elliotson on, 851.

Ricci, Professor, account by, of a female who lived upwards of two years and a half without food, 572.

Rigby, Dr. on the structure of the placenta, and the connexion between the foetal and maternal vessels, 527.

Robertson, Mr. on the advantages to be derived from the classification of labour cases, 77.

Rostan, M. notice of the appointment of, to the chair of clinique interne, 512.

Ross's, Mr. illustrations of the mechanism of parturition, reviewed, 182.

Royal Institution, abstracts of lectures delivered at the : Mr. Cartmuel on improvements in the manufacture of salt, 29;

Mr. Brunel's mode of constructing the arches of bridges, 30; the Marquis Spineto on the origin of the Egyptian worship of animals, 125; Captain Basil Hall on a new construction of paddle-wheels, *ib.*; Dr. Faraday on the action of lime, carbonic acid, and water, on each other, 191; Dr. Turner on the true equivalent numbers of bodies, 269; Dr. Faraday on a new law of electrical conduction, 479; Dr. Grant on the circulatory system, especially of the lower animals, *ib.*; Mr. Brockedon on the uses of caoutchouc, and more particularly its application to the manufacture of elastic web, *ib.*
 Rudolphi, memoir of, by Professor Link, of Berlin, 586.
 Rumsey, Mr. on the motion of the limbs and increase of temperature after death from cholera, 836.
 Rupture of the stomach, Dr. Elliotson on, 522.
 Russell's, Mr. observations on the testicles, reviewed, 501.

S.

St. Bartholomew's hospital reports, 590, 622, 816.
 Salt, Mr. Cartmael on recent improvements in the manufacture of, 29.
 Sandwith, Mr. on the theory and treatment of scarlet fever, 28.
 Sanson, M. clinique by, on diseases of the eye, 30, 62.
 Sardaillon, M. on a case of asphyxia and death from exposure to the fumes of charcoal, with remarks on the presumption of survivorship, 767.
 Scalp, case of erysipelas supervening on an incised wound of the, 534.
 Scapula, case of dislocation of the humerus backwards on the, 478.
 Schneemann, Dr. on a successful case of transfusion of blood, 215.
 Science, editorial observations on societies for the advancement of, 362.
 ——— chemical, Mr. Murray's manual of experiments illustrative of, reviewed, 617.
 Scirrhus of the stomach, Dr. Elliotson on, 545.
 Scrofula, Mr. Cæsar Hawkins on ulceration of the cartilages of the knee-joint from, 876.
 Sediments, urinary, Dr. Elliotson on, 754.
 Serum and urine in disease, Messrs. Brett and Bird's chemical analysis of the, 567.
 Setons, M. Dupuytren on the treatment of goitre by, 719.
 Shoulder-joint, Dr. Crampton on the pathology of dislocation of the, 242.
 Shoulder, Dr. Bell on a simple mode of reducing a dislocation of the, 642.
 Shrapnell, Mr. on the structure of the os incus, 171.
 Skey, Mr. declaration by, touching his dismissal from the demonstratorship at St. Bartholomew's, 868.
 Skin, account, by Dr. Allen Thomson, of some new experiments by Professor Weber on the sensibility of the, 791.
 Sleep, Dr. A. P. W. Philip on the nature of, 695.
 Small-pox, Dr. Loy on the frequency of the occurrence of, after vaccination, 47.
 ——— confluent, Mr. George on the use of calamine in, 671.
 Small-pox and cow-pox, Mr. Morris on the co-existence of, 834.
 Smilax aspera, Dr. Ashburner on the medicinal virtues of, 350; Mr. Belinaye on, 353.
 ——— Dr. Cove on, 501.
 Smith, Mr. letter from, on the subject of self-supporting dispensaries, 839.
 Smith, Dr. Gordon, notice of the death of, 845.
 Solly, Mr. on the advantages of the art of drawing to the medical student, 802.
 Sore throat, case of, with dysphagia, loss of voice, and obstructed breathing, for which laryngotomy was performed, with the appearances after death, and remarks by Mr. Arnott, 223.
 Spence, Mr. practical remarks by, on dysentery, 73, 113.
 Splints, Mr. Grantham on a new form of, for the arm and forearm, 532.
 Spleen, Dr. Elliotson on diseases of the, 457.
 Spackman, Mr. on a case of cyanosis, with an account of the morbid appearances, 737.
 Sprengel, Kurt, notice of the death of, 400.
 Stanley and Mayo, Messrs. account by, of their examination of the Hunterian preparation at the College of Surgeons, with a view to ascertain the structure of the placenta, 353.
 Statistics, medical, Dr. Gregory on, suggesting a registry of the causes of death, 19.
 Sting, effects of the, of a tarantula, 843.
 Stomach, diseases of the, Dr. Elliotson on the morbid appearances in, 513.
 ——— Dr. Elliotson on scirrhus of the, 545.
 Stomach, chemical examination of the contents of the, in a case of reputed poisoning, 861.
 Stone, account of an operation for, in a child —cystitis (?) 623.
 ——— Dr. Elliotson on the symptoms of, in the bladder, 817.
 Strangulation, case of, with remarks by M. Dupuytren, 126.
 Subclavian, ligature of the, performed with success, for a false consecutive aneurism of the left axillary artery, 325; another

case in which a ligature was placed on the axillary artery, 857.
 Suicide, statistics of, in France, 123.
 Surgeons, college of, regulations by the, respecting lost diplomas, 26.
 ————— notice of the appointment of Mr. Guthrie as president, and of Messrs. White and Andrews as vice-presidents, for the ensuing year, 544.
 ————— statement by the council, in pursuance of a resolution "that an exposition of the state of the college be from time to time made to its members," 779.
 ————— statement on behalf of the royal college of, in Edinburgh, 216.
 ————— Edinburgh, the claims of, to practise as apothecaries in England, considered, 207, 391.
 Survivorship, M. Sardaillon on the presumption of, 767.
 System, circulatory, Dr. Grant on the, especially of the lower animals, 479.

T.

Tarantula, effects of the sting of the, 848.
 Tartar emetic, the symptoms of inflammation of the lungs, in a boy, successfully combated by a large dose of, 159.
 Tardif, M. further particulars respecting the attempted assassination of, 258.
 Taynton and Williams, Messrs. on the bite of the viper, 464; on a case of great enlargement of the tongue, 465.
 Teeth, Dr. Asbburner on the, as a source of health or disease, 425.
 Testicles, Mr. Russell's observations on the, reviewed, 501.
 Test tubes, on the presence of arsenic in, 400.
 Tetanus, Dr. Murray on a case of, with remarks on the division of nerves as a method of cure, 15.
 Tetanus, traumatic, Mr. Dehane on a case of, successfully treated with carbonate of iron, 799.
 Things as they were before 1815 (editorial article), 297.
 Thomas, Mr. of Liverpool, on the legal claims of general practitioners, 574.
 Thomson, Dr. Allen, account by, of some new experiments on the sensibility of the skin, by Professor Weber, of Leipzig, 791.
 Tibia, case of fungus hamatodes of the head of the, 511.
 Tod, Mr. on the anatomy and physiology of the organ of hearing, reviewed, 150.
 Toogood, Mr. account by, of a case in which a female catheter accidentally slipped into the bladder, in drawing off the water, 837.

Tongue, Messrs. Taynton and Williams on a case of great enlargement of the, 465.
 ————— Mr. Collier on a case of enlargement of the, 641.
 Tonsillitis, Dr. Elliotson on, 33; attended with ulceration, 35.
 Tonsils, Dr. Elliotson on enlargement of the, 35; fœtid breath, arising from affections of the, 36.
 Toxicology, Dr. Clendinning on the present state of, 440.
 Tracheitis, Dr. Elliotson on, 65.
 Transposition, congenital, of the viscera, Mr. Hardy on a case of, 79.
 Traill, Dr. on a case of hydrocephalus, 434.
 Truss, improved, Mr. Chipman on an, 835.
 Tumor, osteo-sarcomatous of the lower jaw, case of, cured by operation, 590.
 Tumors, vascular, Mr. Phillips on, 7.
 ————— fibro-cellular, of the uterus, M. Dupuytren on, 184; his reasons for abandoning the ligature, and employing excision for the removal of, 187; definition of— their various situations, 188.
 Turner, Dr. on the true equivalent numbers of bodies, 269.
 Tyerman, Mr. on a case of difficult labour, followed by hysteritis, 701.
 Tympanitis, Dr. Elliotson on, 456.

U.

Ulcers, malignant, account of the preparations of arsenic employed by M. Dupuytren in the treatment of, 512.
 Ulceration of the stomach, Dr. Elliotson on, 521.
 University of Edinburgh, memorial of the senatus academicus of, to the secretary of state for the home department, 396.
 Universities, old and new, editorial observations on, 618.
 Urea, Mr. Rees on the presence of in the blood, 676.
 ————— on the process for the detection of, in reply to Messrs. Brett and Bird, 765.
 ————— Messrs. Brett and Bird on the presence of, in the blood, 703.
 ————— in reply to Mr. Rees, 805.
 Urethra, account by M. Vidal de Cassis of a case in which he extracted a pin from the, by the tour de maître, 249.
 Urine, Dr. Elliotson on the causes of an excess of urea in the, 753.
 ————— Messrs. Brett and Bird on the chemical constitution of, in various diseases, 385.
 Uterus, Mr. Hughson on the nature of the venous openings in the, and on the priority of their discovery, 115.
 ————— clinical observations by M. Dupuy-

tren on fibro-cellular tumors of the, 184 ;
case of spontaneous reparation of a poly-
pus of the, 187.

V.

Vaccination, notice of the decrease of, in
Paris, 27.

———— Dr. Loy on the frequency of
the occurrence of small-pox after, 47.

———— Mr. Brown on the insecurity
of, 517.

———— in whooping-cough, Mr. Cheva-
lier on, 321.

Valetudinarium, the Gower-street, editorial
remarks respecting the, 260.

Veins, uterine, Mr. Hughson on the aper-
tures in the, 202.

———— two cases of accidents from the ad-
mission of air into the, during surgical
operations, 269.

Velpeau's, M. embryologie, ou ovologie hu-
maine, reviewed, 435, 537.

Viper, case of recovery from the bite of, re-
lated by Messrs. Taynton and Williams,
464.

Viscera, Mr. Hardy on congenital transpo-
sition of the, 79.

Vision, double, M. Prevost on, 266.

Vomiting, œsophageal, Dr. Marshall Hall
on, 421.

W.

Waller, Dr. on the bandage in parturition,
201.

Watson, Dr. clinical lecture by, on facial
palsy and anæsthesia, 558.

Weber, Professor, account by Dr. Allen
Thomson of some new experiments by, on
the sensibility of the skin, 791.

Williams, Dr. correspondence between, and
the secretary of state, on the propriety of
remunerating medical practitioners for in-
formation required of them by the factory
commissioners, 365.

———— on a case of melanosis, 434.

Wodsworth, Rev. Mr. letter from, regarding
certain statements in an editorial notice
on the Gower-street school, 303.

———— editorial observations
on a letter from, on the subject of the
Gower-street school, 329.

Worms, on the discharge of, from various
parts of the body, 471.

———— Dr. Elliotson on the varieties of, found
in the human intestines, 689.

X.

Xeroma conjunctivæ, Mr. Mackenzie on, 44.
Zoological society, annual report of the, 192.
